To most people the word fermentation is so intimately associated with the manufacture of beers and wines, that it may seem strange it should have anything to do with such a dissimilar industry as tanning. We shall see, however, that fermentation plays a very important part in that industry. I shall not attempt to do more than indicate the present state of our knowledge of the different fermentations which occur in the manufacture of leather, briefly touching on the principal points, and giving references to the latest researches.

Looking up work already done in any subject, especially under modern conditions of a multiplicity of scientific journals and specialisation of subjects, occupies a considerable amount of time. The work, however, must be done, or frequently after months of experiment one finds that some other worker has been over the ground perhaps years before, and that the time we have spent is practically wasted. It is mainly with the object of helping in some degree in this way that I have ventured to collect these

few references bearing on fermentation in the leather industry.

Fermentation, as it affects the tanner, may be divided into two classes:—

(1.) Fermentations which are injurious, and which it is desirable to prevent.

(2.) Fermentations which are essential or helpful, and which it is desirable should go on in a regular and certain manner.

Everyone is aware that after a skin leaves the animal's back it begins to decompose (unless precautions are taken) in a time long or short, according to the temperature.

We may call this the first fermentative action met with in the leather industry, for it is very difficult to draw any hard-and-fast line between the processes of putrefaction and fermentation as usually understood. Putrefaction is always accompanied by the presence of micro-organisms, but fermentation may be due to the presence of unorganised ferments or enzymes.

Either\* considers that a specific putrefactive ferment attacks each constituent of the hide, all the putrefactive organisms utilising the easily soluble albuminoids of the skin as nutrient material. Blood and lymph are the constituents of the fresh hide most liable to putrefaction, and as the germs of putrefactive bacteria are always present in the air, they begin to develop in these materials. Although the putrefaction commences from both surfaces of the skin it is a curious fact that it begins usually on the "grain" side, notwithstanding that this is protected by the hair. The bacteria obtain access by the sweat pores and begin to liquefy the layer of cells between the epidermis and the grain; on the flesh side they enter by the blood vessels and lymphatics, and along these the putrefaction is quickly communicated to the interior of the hide. The intercellular substance or corium and the hide fibres are more stable bodies, but finally the putrefaction spreads from the vessels to the corium, causing it to liquefy; and last of all the hide fibres themselves are attacked and the skin becomes an amorphous semi-fluid mass.

The subject of putrefaction is a large one, the number of bodies formed being very numerous, while the several species of bacteria which cause the decompositions have been little investigated. The drawings, Fig. 1, show bacteria and organisms observed by the author in putrefying skin in 1886. The most constant products† which make their appearance in putrefaction are *leucin*, and probably some of its homologues, tyrosin, the volatile fatty acids of the series  $C_nH_{2n}O_2$  (formic, acetic, propionic, butyric, valeric, caproic, &c.), ammonia, some of the compound ammonias (ethylamine, propylamine, amylamine, trimethylamine)  $CO_2$ ,  $H_2S$ ,  $H$ , and  $N$ .‡

Of course the object of the tanner is to preserve the skin from the action of these destructive ferments. If it is not to be tanned immediately, the simplest methods of preservation are either drying, or the application of salt. In both these cases the bacteria are not destroyed, their action is merely arrested. In hot countries the hide must be preserved from putrefaction while drying, and for this purpose various antiseptics are used, for example, sodium arsenate, a solution of which is applied to the skin before it is stretched out to dry. These skins form the "arsenic kips" of commerce.

In the commercial application of antiseptics, the chemist has proved a valuable ally to the tanner, and of late years, numerous compounds have been introduced for this purpose.§

‡ Acts, ix. 43; x. 6.

The value of many of these different antiseptics has been admirably discussed by Eitner (*Antiseptik in der Gerberei*, *Der Gerber*, xv.), to whose work I must refer you.

The "soaks" are naturally rich in putrefactive ferments, indeed in the summer time it frequently happens that dried skins cannot be thoroughly softened before they begin to putrefy and lose weight.

Here certainly the careful use of some antiseptic may be made the means of controlling their working and of saving a large amount of loss to the tanner. Creolin (a coal tar product distilling over between 170° and 280°) is a material easily and cheaply applied to check the action of bacteria which may be present naturally in the water used by the tanner, or whose presence is due to contamination from drainage.

Fig. 1.

Fig. 1.—Shows organisms observed by the author in putrefying skin in 1886.

a. Swift, moving, darting animalcule, some with irregular outline.

b. A vibrio quite straight and moving very slowly,  $\times 500$ .

c. A large infusorian.

d. A colourless piece of jelly shaped like a dumb-bell. All these appeared in three days in skin placed in a little water, temperature about 20° C.

Five days.—Most striking feature was the increase of vibrios, besides many large infusoria.

e. Large infusorian, apparently double, slow rolling motion.

f. and g. The same in different positions.

Seven days.—Still more vibrios, liquid crowded.

Ten days.—Vibrios clustered round a small particle of matter, whole mass of skin disappeared.

m. Very transparent trembling animalcule, with short darting motion, in large numbers.

From the "soaks" the skin passes to the "limes." It would naturally be thought that here at least it would be safe from the action of destructive bacteria. This, however, is not always the case, for although freshly-made lime liquor or milk of lime is an antiseptic,\* yet it is capable of dissolving the corium of the hide, and as soon as it has taken up a sufficient quantity, which combines with it to form ammonia compounds, scarcely a better medium could be found for the nutriment of certain organised ferments.

It is not, however, until the lime gets really old or putrid that it has a destructive action on the skin; on the contrary the bacteria in limes have a beneficial effect up to a certain point. It is well known that a newly-made lime

liquor is too harsh and sharp in its action, especially on "green" skins, i.e., skins with little or no lime in them.

After a time it becomes what is known as "mellow," in which condition the fibres exert a more favourable reaction on the fibres of the corium, and at its whole substance wears a new firmness, and the surface of the skin appearing to close the pores and thus prevent the rapid effect. This "mellowness" has also a great influence on the action of the bacteria, and it is of great importance to know how far this mellowing process of the skin may be carried. I have been several times investigating their behaviour and properties, in a work yet to be published.

In the next process, that of "bating," the bacteria play a more important part, and may be said to form a second category, viz., helpful to the tanner, though from the very nature of the material used, it forms a nidus for various putrefactive ferments, and is therefore dangerous. The materials usually employed are boiling and dog-bone; the former of these is sharp and piercing in its action, while the latter has a more softening action on the skin. In both bates, however, a rapid solution of the gelatinous and albuminous hide substance (corium) takes place. The hide fibres, however, are not attacked until all the nutrient material in the liquid has been consumed by the bacteria.

Eitner (*Der Gerber*, xv., 158) states that a sterile bate is without action on the skins, and appears in that article to attribute the entire working of the bate to the action of micro-organisms. He seems to have based his conclusions on experiments with an old bate sterilised with creolin, which he found had no action on the skins. If, however, a fresh bate be made and boiled for half-an-hour, then allowed to cool to 90—95° F., it will be found to have a considerable action on the skins, though not so rapid a one as the unboiled bate. The boiling kills all organisms, and fresh ones have not time to develop from spores still remaining before the experiment is at an end.

Lately, the action of unorganised digestive ferments in the dung has been found to be considerable. This bating is an exceedingly complex process. The action appears to be threefold:—

(i.) A purely chemical action of the soluble salts present in the bate on the lime in the skin.\*

(ii.) An action due to organised ferments.

(iii.) An action due to unorganised ferments.

The precise amount of influence each of these actions has on the skin is difficult to assign. The chemical action of the ammonia compounds dissolves the lime remaining in the skin, but the simple removal of the lime is not sufficient, as may be shown by removing it completely with dilute hydro-chloric acid or other similar means, and washing perfectly free from acid in distilled water. When tanned such a skin is hard and brittle.

The organised ferments or bacteria, of which there are many species in the bate, probably act on the skin by secreting soluble ferments which have the power of dissolving hide fibre. I have isolated in plate cultivations several species which liquefy the gelatine.

If skins are allowed to lie in the bate, zoogloae of these bacteria collect in the folds and attack the fine "grain," so that the leather is covered with lines and markings or "flaked." Thus the operation is a very critical one, requiring careful watching; under certain atmospheric conditions and at a temperature of 35—40° C. the skin, if only left a short time too long, will completely melt away. The more skin substance is dissolved in the liquid, the more rapid and pronounced the bacterial action becomes.

\* One kilo. of lime (prepared from marble and slaked) in 20 litres of water has been found to destroy the bacteria of swine fever, hen cholera, and glanders.

So far as is at present known the unorganised ferments in the dung, besides those which are secreted by the bacteria, are mostly digestive ferments\*—pepsine, pancreatine, and trypsin, certain quantities of which pass out of the animal's body in an unchanged condition. Of these *pepsine* only acts in an acid solution, and although fresh bate liquor is faintly acid to litmus it quickly becomes neutralised by the lime in the skins, so that the action of this ferment can only be limited in extent. *Pancreatine*

will act in a neutral solution, and has, therefore a considerable effect on the skin.

I find by experiments with the purified ferments that their action is very slow compared with the bate itself. Two portions of the same skin were taken, one of them was treated with a 1 per cent. solution of pepsine acidified with 0.2 per cent. of hydrochloric acid; the other in a bate liquor of dog's dung, both at a temperature of 40° C. (104° F.). At

the end of one hour the skin in the pepsine solution was considerably "fallen," but that in the manure solution was bated nearly away, i.e., the greater part of it was dissolved.

A 1 per cent. solution of pancreatine (Merck's) was found to act far more rapidly than pepsine. At 10° C. in a neutral solution the skin fell rapidly, and the action continued even in the cold. In this experiment it was found that in 15 hours the liquid was swarming with minute bacteria. In order to guard against the influence of bacteria a similar experiment, at the suggestion of Mr. H. R. Procter, of the Yorkshire College, Leeds, was tried with the addition to the pancreatine solution of 1.5 per cent. of chloroform; this prevents the development of bacteria, while it does not interfere with the action of the pancreatine. The skin was reduced as before, but in neither case had it the peculiar touch of a "pured" skin, nor were the characteristics of the leather the same.

There is a wide field of research open in the chemistry and bacteriology of bating, but from the present state of our knowledge it is quite evident that it is well nigh impossible to produce commercially an artificial bate which shall possess similar properties to the ordinary dung bate.† It

will be found that most of the substitutes proposed have fulfilled only one of the conditions, and none of them have combined properties which are evidently essential.

The next fermentive process, viz. "Drenching," has been described and investigated by myself (this Jour. IX., 27), and more recently in conjunction with Mr. W. H. Willecox, B.Sc. (this Jour. XII. 422), and the work is still being continued. I shall, therefore, pass on to the next process the skin goes through, viz., the tanning process proper.

From the drench (which is, however, only used for certain classes of leather) the skin usually passes directly into the tan liquor, and carries with it vast numbers of fermentive organisms, so that it might naturally be supposed some kind of fermentation would result. This is so, for during tanning infusions of nearly all vegetable tanning materials undergo fermentation, with formation of a little alcohol, gallic, butyric and lactic acids accompanied by evolution of carbon dioxide. In the early days of scientific investigation in the tannery, Pelouze\* attributed these changes to the oxygen of the air, and even so late as 1892 this theory received support. F. G. Reissinger (*Deutsche Gerber Zeitung*, xxxii. 93) endeavoured to show that moist pine bark absorbed oxygen with the production of volatile acids. Eitner and Jahoda (*Der Gerber*, xviii. 245) showed that the absorption of oxygen was a mechanical one, due to the resinous matter of the bark, and that the volatile acids were produced by the action of bacteria.

It was naturally supposed that the bacteria decomposed the tannin itself, forming acids and gases. Tannins were

\* Ann. Chim. Phys. 1834.

known to be glucosides, and as such easily capable of fermentation. But in 1886 B. Kohnstein and Simand (Der Gerber, xii., 253) showed that these acids are not produced from the tannin, but are the result of a fermentation of the extractive matter\* which accompanies the various tannins. In order to prove this they absorbed the tannic and gallic acids and colouring matter of a tan liquor by means of freshly ignited magnesium oxide. They sterilised the liquids by boiling, and inoculated the clear filtrate, which contained the extractive matter but no tannin, with a lactic acid ferment, at the same time inoculating the original liquor with the same ferment. The liquids were kept on the incubator for 14 days. At the end of this time they found the amount of tannin in the original liquor practically unchanged, while both liquids contained a considerable quantity of acid. More acid, indeed, was produced from the liquid free from tannin than in the one containing it. They also noted that, although moulds developed freely in an exposed infusion of tannin (oak bark) in a day or two, they did not develop in the liquid deprived of tannin, even after eight days.

In 1889 the author compared a sumac infusion exposed to the laboratory air with a similar infusion sterilised and exposed to filtered air. In the first the common mould *Penicillium Glaucum* quickly developed, and in 23 days 80 per cent. of the tannin was destroyed. In the protected infusion after 23 days the total amount of tannin was 0.3 per cent. less than at the beginning of the experiment. This loss was no doubt due to the boiling (several times) required to sterilise the liquid.

In contradiction to the experiments of Kohnstein, two French chemists, Messrs. Collin and Benoit, in 1888 endeavoured to show that unsterilised hide always caused fermentation of the tan liquors, changing the tannin into gallic, butyric and lactic acids. They proposed to prevent this fermentation by the addition of minute quantities of mercuric iodide to the liquors.

Eitner, criticising their conclusions (Der Gerber, xv., 1, &c.), denies that the bacteria of unsterilised hide have the power to decompose tannin.

He added decomposing blood albumen to a tannin infusion, and found that only the tannin actually combined with the albumen, and thus precipitated, was removed from the solution, and that when moulds were excluded, the remaining tannin did not disappear, a proof that the putrefactive ferments in decomposing blood exercise no influence on the tannin. In hardly any instance do Eitner's experiments corroborate the statements of Collin and Benoit, indeed it seems certain that these bacteria instead of destroying the tannin actually preserve it, as moulds, which easily decompose tannins, refuse to grow in the presence of the bacteria.

The fermentation of tannin is not, however, due to moulds alone, several species of saccharomyces or wild yeasts attack tannin infusions, and I have isolated in a plate cultivation from sumac infusions a micrococcus which ferments them. This organism grows well in peptone and sugar solution, but will not grow in beef broth. I strongly suspect this to be the organism which ferments sumac and gallnut infusions with formation of gallic acid and evolution of CO<sub>2</sub>. Infusions of these materials ferment and lose their tannins very quickly without the presence of moulds or saccharomyces.

As far as I know, none of these organisms and their products have yet been investigated, and as different tannins ferment in different ways, some being susceptible to fermentation, like pine and oak barks, and divi-divi, others difficultly fermentable, like larch and hemlock, so the amount of work to be done before all these changes are understood is enormous.

We may conclude, however, that the presence of micro-organisms in tan liquors is essential to the proper progress of the tanning process, (1) by causing the formation of acids which are essential for many leathers; (2) by prevent-

ing the development of moulds. Besides those in the text, I give at foot<sup>1</sup> references to other researches on this subject.

It is a cause for reproach to English tanners that most of these are by German and Austrian chemists; I am glad to say that we are now endeavouring to regain lost ground, and that the work now being carried on in the Leather Industries Laboratory at the Yorkshire College, Leeds, under the able management of Professor H. R. Procter, will, ere long, give us a place in the front rank of all nations.

#### DISCUSSION.

Mr. CARLELLA inquired if Mr. Woods had ever used a South American wood known as Quebracho, said to contain as much as 19 per cent. of tannin?

Mr. CLOWES remarked that in one of his earlier communications Mr. Wood had spoken of a certain organism which he had detected, and of the identity of which he was not certain. He would like to know if, upon further examination, the organism had proved to be a new one, or whether it had proved to be one already known. He believed Mr. Wood had had some communication on this matter with other gentlemen who were working in connection with micro-organisms; and numbers would be interested to know what the results of those communications were. The majority of the members present were placed in a very difficult position, as they knew but little of the work placed before them by Mr. Wood. Not only were they unfamiliar with the processes of the tanning industry, but they also were not in a position to learn the newer ideas

\* A loose term for soluble bodies accompanying tannins, some of which reduce Fehling's solution.

<sup>1</sup> Der Gerber, x., 1884, 54, 102; XI., 1885, 98, 112; XIII., 1887, 245; XVIII., 1892, 215. Dine Polyt. Journ., 256, 38, 42, &c. H. Trimble, Index to the literature of the Tannins, in 'The Tannins,' Philadelphia, 1892.

with regard to those processes which Mr. Wood had placed before them. That gentleman had done the section a great service in a highly summarising, as he had done, the new processes, and also in giving them references to the papers in which the different results had appeared. This communication would be very useful to those who wished to take up research work in connection with tanning. It would enable those who wished to get the latest information to acquire it with little trouble, and thus to avoid undertaking work only to find that it had already been done. As to the work which Mr. Wood said was being done at the Leeds College under Mr. Procter, he regretted that similar facilities were not afforded at the Nottingham University College.

The CHAIRMAN said it was Mr. Wood's good fortune to frequently visit the Continent, so that he was constantly coming in contact with the professors interested in these experiments, and the section were very fortunate in having him before them to give them his experiences.

Mr. Wood, replying to Mr. Canalia's question, said that a large quantity of Quebracho was used. It was used more on the Continent, however, than in England. The wool was estimated to contain about 24 per cent. of tannin, but it was so hard that special machines had to be used for cutting it up into shavings, so that the extract was in more general use. The extract contained about 45 per cent. of tannin.

With regard to Dr. Clowes' question about the bacteria to which he had made reference at a previous meeting, he had had some conversations with Dr. Frankland at the British Association meetings in November, as to its identity, and that gentleman advised doing the work by another method. It was now in a pretty forward state; he was working upon it in conjunction with Mr. Wilcox.

With reference to the Leeds Leather Laboratory, it was assisted by the Leeds Leather Trades' Association, besides a grant by the college. There were many more tanners there than in Nottingham.

The CHAIRMAN drew attention to the fact that it had been decided that members of the section should be at liberty to place interesting questions upon the agenda paper for discussion at the meetings. He hoped that good might result from the movement.

Meeting held at the Queen's Hotel, Leeds, on Monday, March 5th, 1894.

PROFESSOR ARTHUR SMITHHELLS IN THE CHAIR.

## ON THE MORDANTING OF WOOL WITH CHROMIUM. PART III.

By L. LIEFCHT AND J. J. HUMMEL.

(See also this Journal, 1893, 240 and 332.)

Among the various chromic oxide salts the first to be considered is chrome-alum,  $\text{Cr}_2(\text{SO}_4)_3 \cdot \text{K}_2\text{SO}_4 + 24\text{H}_2\text{O}$ . Although seldom or never used by woollen dyers, this salt has long been employed by calico-printers, who already, more than 40 years ago, recognised the necessity of applying chromium in some other form than that of potassium bichromate, wherever, indeed, the oxidising property of the latter was found to be injurious, or was not beneficial. At one time a very expensive chemical, and consequently excluded from use in practice, it has now for many years been the custom of the calico-printer's colourist to prepare chrome-alum by reducing potassium bichromate in the presence of sulphuric acid, with glucose, starch, glycerin, &c.

As early as 1851 C. Koechlin made experiments with chrome-alum, not only as a mordant for cotton, but also for wool. His results appear to have been very unsatisfactory, for he says: "L'alun de chrome est le moins convenable des sels pour fournir l'oxyde. Le nitrate donne de meilleurs résultats." For wool (probably woollen printing is meant) he recommends the use of chromium acetate with the addition of one equivalent of oxalic acid; he finds the oxalate and the nitrate to be the best mordants for wool.

Gehe recommends chrome-alum in place of bichromate of potash, because, he says, it is cheap, does not make the wool hard and brittle, and it gives level colours which do not rub off so much. Peisert also prefers chrome-alum to bichromate of potash, because he finds it to yield more level colours, and he recommends it to be used with the addition of a little sulphuric acid. Jolet, too, recommends chrome-alum for wool, and states that the fibre absorbs the salt as such, not as a basic salt or as a hydrate. He considers that the salt is decomposed in the dye-bath only, for although the chrome-alum is not washed out by cold water it can be removed by hot water. The addition of cream of tartar he deems to be unnecessary, although it is absorbed unchanged by the wool to the extent of one-fourth the weight of the chrome-alum employed. Curiously enough Jolet says that chrome colours are not very fast to light. Gauswilt and Kertesz recommend the use of cream of tartar as an assistant. Depierre considers all chromic oxide salts to be inferior mordants to bichromate of potash. According to Herzfeld green solutions of chrome-alum give up more oxide to the fibre than violet solutions, and he finds it desirable to employ large amounts of cream of tartar. Kay and Bastow find, on comparing bichromate of potash with chrome-alum as mordants, using equivalent amounts, that the latter gives up to the fibre twice as much  $\text{Cr}_2\text{O}_3$  as the former; they also observe that by employing larger amounts of chrome-alum, e.g., 20 per cent. instead of 10 per cent., less chromium is fixed, e.g., 53.07 per cent. instead of 63.87 per cent.; and with the use of 3 per cent. tartaric acid the amount fixed is reduced as low as 30.7 per cent. Koepp enumerates the following advantages in connection with the use of chromic oxide mordants (referring no doubt to the use of chromium fluoride): the wool preserves a soft handle and is readily wetted out and there is no fear of over-chroming. Knecht, Rawson, and Loewenthal consider that part of the chromium sulphate is probably simply absorbed by the wool fibre and is not fixed in a permanent manner, and thus account for the poor results obtained in dyeing. Cochenhausen recommends the use of 4 mols. cream of tartar; Witt also recommends tartar, but does not find chrome-alum to be an advantageous mordant. Previous experiments in the Yorkshire College dyehouse have shown that cream of tartar, tartaric and oxalic acids are all useful assistants with chrome-alum.

Notices of Papers and Communications should be addressed to the Hon. Local Secretary.

### SESSION 1893-94.

April 2nd:—

Messrs. Hummel and Perkin. "The Tinctorial Properties of some Indian Dyestuffs." Part I.  
Annual Meeting for Election of Officers.

May 7th.—Mr. H. R. Procter. "The Qualitative Recognition of Tanning Materials."

Such is a very brief *résumé* of the published references to chrome-alum as a mordant for wool.

The difficulties connected with the subject are not inviting, and yet further study seemed to us desirable, especially when it is remembered that bichromate of potash baths are only exhausted to the extent of one-third, and because a good non-oxidising chromium mordant is required for all these colours which are in any way sensitive to oxidising influences, *e.g.*, wooded colours, alizarin blue, &c.

Further, it appeared interesting to learn, if possible, more regarding the reactions which occur during the mordanting of wool, about which we still know so little, and which probably cannot be fully explained until we have a clearer knowledge of the chemical constitution of wool.

#### A.—CHROME-ALUM. $\text{Cr}_2(\text{SO}_4)_3 \cdot \text{K}_2\text{SO}_4 + 24\text{H}_2\text{O}$ .

The differences in the opinions expressed regarding the value of chrome-alum as a wool-mordant are due no doubt to two causes:—first, the different percentages, reckoned on the weight of wool employed; second, the concentration of the mordanting bath and the quality of the water. Here too, as in the case of the bichromate of potash mordant, little or no attention has been paid to the ratio which ought to subsist between the amounts of colouring matter and mordant employed.

In the following experiments 10 per cent. chrome-alum was usually taken, *i.e.*, about equivalent to 3 per cent. bichromate of potash. For each trial 10 grms. wool and 600 cc. Leeds water were employed.

**Experiment 1.**—Wool was mordanted  $1\frac{1}{2}$  hours with 10 per cent. chrome-alum. As the temperature of the bath rose, the colour of the solution gradually altered, the violet tint changing to green. This of course was not surprising, for it has long been known that on heating solutions of the violet modification of chrome-alum to a temperature of  $55^\circ$ – $65^\circ$  C. it changes into the green modification. If the solution was heated without any wool being immersed in it, the same colour changes were noticed, and yet a distinctly yellowish-green was exhibited by the solution containing the wool. Both baths remained clear to  $80^\circ$ – $82^\circ$  C., but at this temperature the bath containing wool began to show signs of turbidity, which soon rapidly increased so that the solution became quite opaque. The precipitate was excessively fine and had by no means the ordinary flocculent character of chromic hydrate. Now it has long been known that wool has the property of absorbing or attracting in a mechanical manner very finely divided insoluble matter in suspension, and this feature was strikingly shown in the present instance. Before the appearance of the turbidity the wool scarcely showed even traces of any green tint, but from this point it rapidly acquired a yellowish-green colour. At a temperature of about  $95^\circ$  C. the solution became clear again, and, after boiling a little, it was perfectly limpid and almost colourless, the wool having mechanically fixed nearly the whole of the precipitate. When the bath was allowed to cool, it contained only a small quantity of a pale green precipitate, and if the wool was kneaded and pressed in the liquor with the fingers a little of the adhering precipitate could be removed from it; still even with vigorous washing the major portion still remained attached to the wool, colouring it a pleasing shade of yellowish-green. The chrome-alum solution not containing wool gave no precipitate even after long boiling, and remained clear when cold.

**Experiment 2.**—The same experiment as the foregoing was repeated in every detail except that 10 grms. bleached cotton was employed instead of wool. In this case the bath remained perfectly clear both when boiling and when cold, and after washing, the cotton appeared perfectly white.

**Experiment 3.**—The same experiment was again repeated, this time using 10 grms. boiled-off silk. Here the same appearances were noticed as in the case of wool, although the decomposition of the chrome-alum was not so great, and the green colour of the silk was less intense than that of the wool.

In order to see if the silk was really mordanted properly or not, a portion was dyed with 12 per cent. alizarin (20 per cent. paste), when a fairly good claret colour was obtained.

The wool of experiment No. 1, and other similar pieces, were dyed with alizarin, logwood, and quercitron bark, but in each case a very poor and practically useless result was obtained.

An attempt was now made to determine analytically the nature of the change which had occurred. The waste liquors of experiments 1, 2, and 3, were analysed, No. 1 being of course filtered. The waste liquor of No. 2 was absolutely unchanged, it still contained the whole of the chromium in the form of chrome-alum.

With respect to the waste liquor of No. 1, however, the average of ten determinations showed that only 14.3 per cent. of the original chromic oxide remained still in solution, so that 85.7 per cent. was partly fixed on the wool and partly in the precipitate. On repeating the experiment with the addition of 10 per cent. sodium chloride to the bath, the decomposition was quite complete, for the waste liquor proved to be entirely free from chromium. Another experiment in which only 5 per cent. chrome-alum was employed, also showed mere traces of chromium in the filtered liquor. A certain relationship seems therefore to exist between the amounts of wool and of chrome-alum, so that, as already stated, when using 5 per cent. of the latter total decomposition is produced, while with 10 per cent. it is affected only to the extent of 85.7 per cent.

The precipitate adhering to the wool was removed as much as possible by kneading with water, then collected on a filter, washed thoroughly, and analysed. It proved to be very difficultly soluble in acids, and was therefore changed into sodium chromate by boiling with an alkaline solution of sodium hypochlorite, then acidified and reduced with alcohol. Analysis showed the precipitate to be a very basic chromic sulphate, the actual results obtained in four examinations being as follows:—

1.  $1(\text{Cr}_2\text{O}_3) + 0.836 \text{ SO}_3$
2. " + 0.819 "
3. " + 0.538 "
4. " + 0.360 "

The varying composition here shown is not surprising, and it is no doubt caused by the different lengths of time taken to heat the bath up to the point of initial turbidity.

Moreover, the last portions of chrome-alum may also become insoluble by long-continued heating at the boiling point.

First thoughts would lead one to expect to find the liberated sulphuric acid in the waste liquor along with the undecomposed chrome-alum. Strange to say, this is not the case entirely, for the facts compel the conclusion that the wool contains free sulphuric acid as well as the basic chromium sulphate.

Suppose we take the mean of the above analyses and consider the basic chromium sulphate to have the composition  $1(\text{Cr}_2\text{O}_3) + 0.666\text{SO}_3$  ( $= \frac{2}{3}$  sulphate). Such a compound is obtained, according to Gimelin, on heating a solution of  $\text{Cr}_2(\text{SO}_4)_3 \cdot 2(\text{OH})_2$  as a pale green precipitate having the composition  $2(\text{Cr}_2\text{SO}_4(\text{OH})_2) + \text{Cr}_2(\text{OH})_6$ , *i.e.*,  $(\text{Cr}_2\text{O}_3 + 0.666\text{SO}_3)$ . Now we have already seen that about 85.7 per cent. of the chrome-alum used is precipitated in the form of basic sulphate of the above composition. Omitting the  $\text{K}_2\text{SO}_4$ , the amount of chrome-alum used contains 0.153 grm.  $\text{Cr}_2\text{O}_3 + 0.240$  grm.  $\text{SO}_3$ , but since 85.7 per cent. of the  $\text{Cr}_2\text{O}_3$  (*i.e.*, 0.13112 grm.) require for the formation of the  $\frac{2}{3}$  sulphate, 0.0457 grm.  $\text{SO}_3$ , there must remain in the waste liquor 0.0219 grm.  $\text{Cr}_2\text{O}_3$  combined with 0.1943 grm.  $\text{SO}_3$ —

$$0.0219 : 0.1943 = 153 : x ; x = 1358. \quad \frac{1.55}{89} = 16.9.$$

therefore the remainder of the chromium must be found in the waste liquor as  $(\text{Cr}_2\text{O}_3 + 16.9 \text{ SO}_3)$ , *i.e.*, as a very acid sulphate. Experiments showed, however, that much

less free sulphuric acid was present than is here indicated. The following experimental data may be cited as typical of many which were made:—

$$\begin{array}{l} a. \quad \text{Cr}_2\text{O}_3 = 0.016, \quad \text{SO}_3 = 0.1033. \\ 0.016 : 0.1033 = 153 : x; \quad x = 188. \quad \frac{188}{80} = 12.35. \end{array}$$

There was, therefore, really present in the waste liquor an acid sulphate of the composition ( $\text{Cr}_2\text{O}_3 + 12.35 \text{SO}_3$ ).

On the wool and in the precipitate there should accordingly be ( $\text{Cr}_2\text{O}_3 + 1.91 \text{SO}_3$ ), calculated as follows:—

$$\begin{array}{l} 0.153 - 0.016 = 0.137 \text{ gm. Cr}_2\text{O}_3 \\ 0.240 - 0.1033 = 0.1367 \text{ gm. SO}_3 \\ 0.137 : 0.1367 = 153 : x; \quad x = 152.7; \quad \frac{152.7}{80} = 1.91. \end{array}$$

Such a compound, however, in spite of its basic character, should be perfectly soluble, an evident contradiction of the facts.

The 0.137 gm.  $\text{Cr}_2\text{O}_3$  present on the wool would require for the formation of  $\frac{2}{3}$  chromic sulphate 0.0477 gm.  $\text{SO}_3$ . By difference, however, there is found to be 0.1367 gm.  $\text{SO}_3$ , hence there must be on the wool 0.1367—0.0477, i.e., 0.089 gm.  $\text{SO}_3$  in the free state.

It seems somewhat difficult to imagine the presence of basic chromium sulphate and of free sulphuric acid in the wool at the same time, but the correctness of this view will be established by experiments to be cited later on. It may, however, be already stated here that long boiling of the green coloured wool with excess of hydrochloric acid did not dissolve off the basic sulphate.

b. On calcining another sample of wool mordanted in chrome-alum, it was found to contain 0.1385 gm.  $\text{Cr}_2\text{O}_3$  (containing a trace of  $\text{Fe}_2\text{O}_3$ ) and 0.164 gm.  $\text{SO}_3$ , from which the following calculation—

$$0.1385 : 0.164 = 153 : x; \quad x = 181.2; \quad \frac{181.2}{80} = 2.265$$

shows that the wool contained the compound—

Since, however, the 0.1385 gm.  $\text{Cr}_2\text{O}_3$  would as  $\frac{2}{3}$  basic sulphate only contain 0.0482 gm.  $\text{SO}_3$ , there must have been 0.164—0.0482, i.e., 0.1158 gm. free  $\text{SO}_3$  in the wool, an amount which is somewhat larger even than that estimated above. In the waste liquor from the wool here analysed there was found 0.0145 gm.,  $\text{Cr}_2\text{O}_3$ , and 0.076 gm.,  $\text{SO}_3$ , which correspond to the compound ( $\text{Cr}_2\text{O}_3 + 10.02 \text{SO}_3$ ).

c. Another similar analysis showed the wool to contain ( $\text{Cr}_2\text{O}_3 + 1.745 \text{SO}_3$ ), while the waste liquor contained ( $\text{Cr}_2\text{O}_3 + 11.16 \text{SO}_3$ ). In this experiment the mordanted wool was extracted for a very long time with distilled water, which may account for the larger proportion of  $\text{SO}_3$  found in the waste liquor.

d. It would be too tedious to cite all the different analyses which were made, but another may be given in which a comparison was made between the behaviour of chrome alum and ordinary potash alum.

*Experiment 4.*—Wool was mordanted with—

a. 9.48 per cent. potash-alum—

b. 10 per cent. chrome-alum.

The alum bath began to be slightly turbid at 73° C., and did not appear to change much afterwards; when cold a good deal of precipitate could be removed from the wool by kneading it with water. The chrome-alum bath began to be turbid at 82° C., the decomposition being specially marked at 85° C., and soon quite complete; 88.8 per cent. of the chrome alum was decomposed. On titration, (a) required 2.56 cc. normal NaOH; (b) required 0.93 cc. Analysis showed the wool to contain ( $\text{Cr}_2\text{O}_3 + 2.238 \text{SO}_3$ ), and the waste liquor ( $\text{Cr}_2\text{O}_3 + 9.01 \text{SO}_3$ ).

*Experiment 5.*—Although the foregoing experiments showed that no good result could be expected by employing basic chromic sulphate, one experiment was made with this

compound, more with the view of demonstrating how very differently wool behaves from cotton. The following two baths were prepared:—

both equivalent to 10 per cent. chrome-alum, and two wool patterns were mordanted as usual. As expected, both solutions decomposed very much, and the wool acquired a fine sea-green colour. The result reminds one forcibly of Chevreul's attempt to colour wool with finely divided carbon, ferric hydrate, &c., and this method of dyeing wool green may certainly be capable of practical application. Both patterns gave poor colours on being dyed and were therefore, as expected, badly mordanted.

*Experiment 6.*—To determine if the potassium sulphate present in chrome-alum exercised any influence, in connexion with the decomposition of the latter, 10 grms. wool were boiled with a solution of pure chromic sulphate equivalent to 1 gm. chrome-alum and prepared as follows: One gm. chrome-alum in solution was precipitated with the equivalent amount of NaOH and the chromic hydrate was well washed and at once dissolved in the equivalent amount of normal sulphuric acid. The appearances observed were exactly the same as in the case of chrome-alum. (The waste liquor contained 0.01346 gm.  $\text{Cr}_2\text{O}_3$  and 0.0774 gm.  $\text{SO}_3$ , therefore the wool and precipitate together contained 0.13954 gm.  $\text{Cr}_2\text{O}_3$  and 0.1626 gm.  $\text{SO}_3$ . Hence the waste liquor contained ( $\text{Cr}_2\text{O}_3 + 10.99 \text{SO}_3$ ), and the wool ( $\text{Cr}_2\text{O}_3 + 2.23 \text{SO}_3$ ).

After mordanting, the wool was well pressed, then steeped in cold distilled water, and boiled again with water repeatedly. It was impossible, however, even after many days, to remove the last traces of acid. The first wash waters were added to the waste liquor before making the analysis. In a subsidiary experiment, bichromate of potash, equivalent to 10 per cent. chrome-alum, was reduced by addition of 4 mols.  $\text{H}_2\text{SO}_4$ , and the necessary amount of starch and the solution was employed for mordanting 10 grms. wool. As was to be expected, the same appearances were observed as in the case of chrome-alum.

*Experiment 7.*—It seemed desirable to determine carefully the behaviour of chromium chloride and nitrate towards wool. These salts were prepared from chrome-alum in the same manner as the chromium sulphate, in order to be quite certain that exactly the same amount of  $\text{Cr}_2\text{O}_3$  was used in each case.

The chromium chloride bath became yellowish green on heating, but remained perfectly clear throughout. The wool acquired a peculiar greenish yellow tint, and had not the appearance of being mordanted at all. Analysis showed that 86.54 per cent. of the chromium remained in the waste liquor, so that only 13.46 per cent. was fixed on the wool.

The waste liquor contained  $\text{Cr}_2(\text{OH})_2\text{Cl}_4$ , hence the wool must have contained the compound ( $\text{Cr}_2 + 18.3 \text{Cl}$ ). This corresponds to ( $\text{Cr}_2\text{O}_3 + 9.15 \text{SO}_3$ ), hence in this case a very acid salt is fixed on the wool. The circumstance that here none of the chromium was precipitated as was the case with chrome-alum, is quite in accordance with the fact that both chromium chloride and nitrate in solution bear the addition of a large proportion of sodium carbonate (up to 2 mols.), without a precipitate being formed.

With chromium nitrate too, a very indifferent mordanting of the wool was effected, the material acquiring even a paler greenish-yellow tint. The waste liquor contained 0.1339 gm.  $\text{Cr}_2\text{O}_3$ , i.e., 87.52 per cent. of the original amount, so that the wool contained only 12.48 per cent.

Both samples of mordanted wool gave poor results in dyeing, a point to which reference will be made when dealing with the effect of adding various acids to chrome-alum mordant.

*Experiment 8.*—According to Havrez, wool may be mordanted to a certain extent even in the cold. In order to test this point, 10 grms. wool were steeped for a month in a solution of 1 gm. chrome-alum in 600 cc. water, and shaken up every day. After thorough washing, the fent was dyed, when it became at once evident that a partial

mordanting of the wool had really occurred. A titration showed that about 11 per cent. of the chrome-alum had been decomposed.

In all cases of mordanting wool with acid salts, as was already observed long ago by Hayez, and referred to more recently by Knecht, the presence of ammonia could be detected in the waste liquors, and this too was observed with certainty, even in the case of the wool mordanted in the cold. The ammonia, however, was not quantitatively estimated. It is well to point out here that in all the analyses of waste liquors given, a portion of the sulphuric acid reckoned as in combination with chromium is really combined with ammonia.

It is not unnatural therefore, to consider that the ammonia which is given off from the wool combines with some of the  $\text{SO}_4$  groups of the chrome-alum and so effects its decomposition. This undoubtedly occurs, but only to a limited extent, and cannot be accepted as a full explanation of the reaction which takes place, otherwise the analyses would not show any disappearance of  $\text{H}_2\text{SO}_4$  from the waste liquor. To avoid any misconception on this point, consider the following typical case, a little more in detail. When wool is boiled with 5 per cent. chrome-alum in solution, the decomposition of the salt is practically complete, as we have seen. A small amount (equal to  $\frac{1}{3}$  mol.  $\text{H}_2\text{SO}_4$ ) is combined with the precipitated  $\text{Cr}_2\text{O}_3$ , so that the waste liquor should contain  $3\frac{1}{3}$  mols.  $\text{H}_2\text{SO}_4$  capable of being estimated as barium sulphate. Such is, however, never the case, as numerous analyses have shown; invariably a large proportion of the  $\text{H}_2\text{SO}_4$  is wanting, and must, therefore, have been taken up by the wool. That such is really the case will be better understood in connection with other experiments still to be cited.

**Experiment 9.**—This experiment was made in order to confirm if possible with more certainty the truth of the conclusions, drawn from the analyses already made, the immediate question to be answered being: what becomes of the  $\text{K}_2\text{SO}_4$  of the chrome-alum. 10 cc. dilute  $\text{H}_2\text{SO}_4$  was exactly neutralised with  $\text{KOH}$ , then made up to 600 cc. with water, and 10 grms. wool were boiled in the  $\text{K}_2\text{SO}_4$  solution. The bath became faintly turbid through the presence of organic matter, but it remained perfectly neutral. The sulphuric acid determined gravimetrically in one half of the bath, amounted to 0.2135 gm.  $\text{SO}_3$ , therefore 0.427 gm. per 600 cc. waste liquor. A parallel determination was made with 10 cc. of the original dilute sulphuric acid employed, and it was found to contain 0.4266 gm.  $\text{SO}_3$ . This complete agreement in the numbers obtained, showed that the potassium sulphate was not absorbed by the wool but remained entirely in the bath. Hence, in all the analyses of waste liquors, the  $\text{BaSO}_4$  due to the presence of the  $\text{K}_2\text{SO}_4$  was invariably deducted, and only the residual  $\text{H}_2\text{SO}_4$  was reckoned as combined with the chromium.

**Experiment 10.**—This experiment was made in order to see if, during the mordanting process, the sulphur of the wool itself might not yield sulphuric acid.

Ten grms. of wool were boiled in a solution of sodium nitrate made by neutralising 10 cc. normal nitric acid with potassium hydrate and diluting to 600 cc. Barium chloride was added to the neutral and slightly turbid waste liquor after acidifying it with hydrochloric acid, but it produced only yellowish white flocks, not in the least like barium sulphate, and when calcined showing traces of iron to be present. This residue only weighed 0.017 gm., and was probably composed of  $\text{BaO}$  and  $\text{Fe}_2\text{O}_3$  rather than of  $\text{BaSO}_4$ . At any rate, such traces of  $\text{H}_2\text{SO}_4$  might be neglected.

It is usually considered that a chrome-alum solution which has become green by heating is dissociated, and this dissociation occurs between  $60^\circ$  and  $80^\circ$  C. Tieckhorne, however, has suggested that the chromatic change is due to basicity of the solution (Chemical News, 24, pp. 209, 211). When he allowed dilute chrome-alum solution to drop into boiling water he observed that dissociation occurred at once (see experiment 19), the solution became opaque and basic sulphate was precipitated, but it dissolved again on cooling. An attempt to repeat this experiment was not

successful, for the solution never exhibited the decided turbidity which invariably appeared whenever wool was present. According to Krieger the green solution contains  $(\text{Cr}_2\text{O}_3 \cdot 2\text{SO}_3)_2$ , while Stewart states that 8 mols. chrome-alum are decomposed into—

Again G. D. van Claef (1881) showed that green chrome-alum solutions were separable by dialysis into two parts, an acid sulphate diffused through the septum while a basic sulphate remained behind. Berzelius had previously shown a similar state of things to exist in connection with ferric salts. Lowel found the presence of green salts saturated only to the extent of  $\frac{1}{2}$ , which corresponds to a tetra-acid chromic salt. The latest work on this subject is that of Recoura, who says: under the action of heat, the oxide combined with three equivalents of acid undergoes a modification which alters its capacity for saturation, so that it can only remain in combination with two equivalents of acid, the third being in the free state, and the liquor becomes green. Since his chromo-sulphuric acid  $(\text{Cr}_2\text{O}_3 \cdot 4\text{SO}_3)_2$  is immediately decomposed on boiling, it can scarcely enter into consideration here. Recoura himself considers that the change from violet to green in the case of chrome-alum solutions depend on the formation of the basic sulphate  $(\text{Cr}_2\text{O}_3)_2(\text{SO}_3)_2$ , to which the corresponding hydrate would be  $\text{Cr}_2\text{O}_3(\text{OH})_2$ .

An experiment was made in which chrome-alum was titrated with normal  $\text{NaOH}$ , and it was observed that a first change of colour really occurred when one-sixth of the  $\text{SO}_3$  was neutralised, and a second change to a decided yellowish-green colour was noticed when one-third of the  $\text{SO}_3$  was saturated. These observations correspond exactly with the appearances noticed during the mordanting process, so that the decomposition of the chrome-alum during the mordanting of the wool can scarcely be explained in any other manner than by considering that the wool gradually absorbs the sulphuric acid from the dissociated green solution with the formation of a more and more basic salt, and that this process continues until the wool under the existing conditions becomes saturated. As above shown, this point occurs when about 8.57 per cent. of the 10 per cent. chrome-alum presented to the fibre is decomposed, and it has already been shown that 5 per cent. is completely decomposed by the wool.

**Experiment 11.**—This experiment was made in order to see if substances similarly constituted to wool would behave in a similar manner towards chrome-alum solutions. The whites of two eggs were beaten to a froth with cold distilled water, and then poured into boiling distilled water. The finely-divided coagulum thus obtained was pressed, well washed, and treated with dilute acetic acid to remove the last traces of alkali, and finally washed again. The coagulated albumen thus prepared was boiled for  $1\frac{1}{2}$  hours with 1 gm. chrome-alum dissolved in 600 cc. water, with the result that exactly the same appearances were observed as in the case of wool, and the albumen absorbed 74 per cent. of the acid present. In another experiment hide-powder was boiled with chrome-alum solution in a similar manner, and the same reactions occurred; the chrome-alum was decomposed with precipitation of a very basic sulphate.

**Experiment 12** was made in order to determine approximately how much sulphuric acid was absorbed by the wool at the point when turbidity of the bath began. 1 gm. chrome-alum was dissolved in 600 cc. water; the solution was heated to  $80^\circ$  C., and then rapidly, but carefully, titrated with normal sodium hydrate. Incipient turbidity was caused by the addition of 2.5 cc., which corresponds to the absorption of 1.25  $\text{SO}_3$ , so that at this moment the bath would contain  $(\text{Cr}_2\text{O}_3 - 1.75 \text{SO}_3)_2$ .

If now the above-mentioned view is correct, namely, that the almost total decomposition of the chrome-alum solution is caused by the absorption of its sulphuric acid by the wool, two modes of preventing it appear possible: (1) the employment of larger amounts of chrome-alum; (2) the addition of acid to the bath.

*Experiment 13.*—Wool was mordanted with 10, 15, 20, 25, 30, 35, and 40 per cent. chrome-alum in the ordinary manner. With increase of concentration of the baths their decomposition was diminished, as indeed was to be expected on physical grounds, so that the solutions containing the largest amounts remained perfectly clear. With the increase in the amounts of mordant used, the separation and fixing of insoluble basic sulphate gradually disappeared; the samples had the appearance of being better mordanted, showing signs of having fixed large quantities of chromium. Instead of the yellowish-green colour observed before, they had now a violet-greenish grey tint, and they gave one the impression that chrome-alum as such was in a state of solution within the wool-fibre.

The samples were dyed with logwood, alizarin, and Persian berries, and the colours obtained became darker and darker, corresponding to the increasing amounts of chrome-alum employed. When examined more carefully, however, the colours were seen to have an irregular, speckled, or seedy appearance, since separate wool fibres had evidently taken up different amounts of mordant, and therefore of colouring matter as well. A microscopic examination showed this peculiarity extremely well, and fibres of every degree of intensity of colour were to be seen, some being almost colourless, others very dark; indeed, similar differences were noticed even in one and the same fibre.

With chromic acid, *i.e.*, bichromate of potash, it is easy to mordant the wool evenly, so that when examined microscopically the individual fibres scarcely differ from each other in depth of colour. With the chromic oxide mordants however such regularity is difficult to attain and is only met with in the very best of this class. No doubt this difficulty has to some extent caused practical wool-dyers to discard chrome-alum. With the dyestuffs above alluded to (logwood, alizarin, and Persian berries) and with the increasing amounts of chrome-alum, the colours varied respectively from pale grey to deep bluish-black, from pale yellowish-chestnut to a dark dull purple, and from straw-yellow to a brownish-orange.

While the question of overchroming, referred to in the last paper, was under consideration, a few experiments were made to see if similar effects could possibly be obtained with chromic oxide mordants, and it may be well to refer to these here.

*Experiment 14.*—The usual 10 grms. wool, divided into six equal pieces, was mordanted with 40 per cent. chrome alum. No. 1 sample was removed from the bath just when it began to boil, No. 2 a quarter of an hour later, and so on; No. 5 was boiled 1 hour, and No. 6, 2 hours. The mordanted samples were well washed, and half of each was extracted several times with boiling water, then dyed with logwood at the boil and finally washed in boiling water. In no case was there formation of lake in the dye-bath, and no overchroming was perceptible. All the mordanted samples had a violet greyish-green tint similar to that of chrome-alum, and the baths showed no signs of dissociation. The dyed patterns varied from a medium to a deep shade of bluish-black with a slight reddish cast in the case of those patterns which had been washed in the ordinary manner with cold water after mordanting. Although chrome alum seems finally to give up a larger amount of chromium to the wool than does chromic acid, the latter gives up more than the former in a limited period.

After pursuing the study of the behaviour of chrome-alum up to this point, we were, through the kindness of Mr. R. Crenier (Verviers) enabled to consult an important though little known paper written by Paul Havrez, entitled "*Étude de l'alunage des laines à teindre*," and which appears in the *Bulletin du Musée de l'Industrie de Belgique*, May and June 1872. Havrez worked with ordinary alum, but in most points his results coincide with the foregoing, although his explanations of the reactions which occur differ from ours. He imitated the somewhat older work of Chevreul who neglected the influence exerted by the amounts of alum employed, and who indeed adopted conditions altogether useless from a practical point of view. For example, he treated 1 grm. wool in the cold with 25 grms.

of a 5 per cent. alum solution (therefore 125 per cent. alum) and then determined the amount of water, alum, &c. in 10 grms. of the bath. Still, Chevreul had already shown that wool absorbed 2.84 per cent.  $\text{H}_2\text{SO}_4$ , of which it could not be deprived; further, he observed the liberation of ammonia or of an ammoniacal product. He considered also that wool was capable of absorbing 1.26 per cent. alum. Previous to Chevreul indeed, Thénard and Roard found that wool could absorb alum as such, *i.e.* without undergoing decomposition.

Havrez studied specially the influence of the relative amounts of alum, wool, and water; then the influence of temperature, and the duration of the action. He worked at a tepid and also at a boiling heat, with amounts of alum varying from  $\frac{1}{100}$ —100 per cent., and after dyeing with various dye-woods, he determined by means of Chevreul's chromatic scale, the effect produced as regards shade, saddening and intensity. Unfortunately he seldom gives positive chemical data so necessary to the understanding of his assertions, and probably for this very reason his otherwise excellent work has for the most part been neglected by chemists.

Havrez observed the decomposition of the alum when employing small amounts, and at first was inclined to attribute it to traces of soda left in the wool from the scouring, the calcium carbonate of the water employed, and the ammonia resulting from the decomposition of the gelatinous principle of the wool; afterwards, however, he adopted a suggestion of the celebrated chemist Stas, and ascribed the cause to the dissociation of the alum. We find, however, that although an addition of acetic acid prevents dissociation, no good results are obtainable in this manner. Further, we disagree with his assertion that an excess of alum acts like an acid which dissolves the alumina, and gives shades which remind one of the reddening of litmus by acid, while small amounts give shades which correspond to the bluing of litmus by alkalis. On the other hand, Havrez rightly maintains that with large amounts of alum, there is fixed in the wool a compound of alumina and sulphuric acid. In our experiments the largest amount of chrome-alum employed was 40 per cent., which gave indeed the darkest colours, and there was therefore no sign of any oxide being dissolved off the fibre. Havrez also observed that wool mordanted for a long time in old alum baths became covered with a white, powdery precipitate, which he regarded as aluminium hydrate. In the case of chrome-alum, our conclusion is, as already stated, that the analogous precipitate is really a very basic sulphate. Havrez states that if a number of mordanting operations are effected in the same bath, the solution acquires an alkaline reaction towards litmus, if for 1 part alum more than 15 parts wool are employed. This does not occur with less than 15 parts wool to 1 part alum, the alumina then remains in solution, and purer, brighter colours are obtained in consequence of the absorption of free sulphuric acid and excess of alum. With less than 7 per cent. alum the action of the basicity of the bath becomes evident, the wool suffers, becomes brownish tinted through alkali, emits odorous gases, and gives only dull colours on dyeing. An addition of acid is beneficial with small proportions (1 per cent.) of alum; this statement of Havrez is also true, and shows how carefully he worked and observed.

Further on there will be an opportunity of showing that with smaller amounts of colouring matter one must use correspondingly smaller amounts of mordants, but at the same time increasing amounts of acid, in order to obtain bright normal colours.

Havrez declared that with small amounts of alum, boiling was not at all necessary, and that he could mordant wool with aluminium acetate at a low temperature. This last point we have not exhaustively studied, but up to the present we have invariably obtained poor results when mordanting at a low temperature. Certainly Havrez both mordanted and dyed in much more concentrated baths than ours, *viz.*, 1,500 parts water per 100 parts wool, a proportion which is probably seldom or never met with in practice. The mordanting action undoubtedly varies according to the concentration of the baths employed, and hence it is

difficult to bring into accord the various statements of different authors, since each has evidently worked under slightly different conditions.

We are unable, however, to confirm Havrez's statement that by using 2 per cent. sulphuric acid with 10 per cent. alum, the dyeing with logwood is hindered; we find that even with 3 and 4 per cent. acid with 10 per cent. chrome-alum, deep colours are obtained.

Havrez concludes, always judging merely from the appearance of the dyed colours, that with the use of 3-7 per cent. alum, a basic sulphate is fixed on the fibre; with more than 7 per cent. a little less alumina and more aluminium sulphate is fixed. The maximum amount lies between 10 and 15 per cent.; larger amounts are said to dissolve off the alumina already fixed, and thus yield paler colours; with 30-40 per cent. alum, deep colours are only obtained after very long boiling.

In explanation of his results, Havrez assumes in the first place that dissociation occurs, thus:—

and he considers the  $\text{Al}_2(\text{OH})_6$  to be present partly in a soluble modification. Further, he considers that the wool takes up these two forms of hydrate in unequal amounts along with free alum. Finally, when several lots of wool are mordanted in a mixture of aluminium sulphate and sulphuric acid, he concludes that the first lots of wool absorb relatively more sulphuric acid, since after some time the bath contains alum only and not any free sulphuric acid; "l'absorption fixe la dissociation, la rend permanente." A bath is poorer in sulphuric acid and richer in basic sulphate, the larger the quantity of wool which is worked in it, either all at once or in successive quantities.

Further reference here to Havrez's work is unnecessary, except to refer the reader to the abstract which occurs in Chas. O'Neill's *Textile Colourist*, Vol. III., 1877, p. 131, and to give Havrez's general conclusions, which are as follows:—

(1.) Strong doses of mordants act in solution as salts (or as salts and acids) after their absorption by wool.

(2.) Weak doses of mordants act upon wool as metallic hydrates, the formation of which is assisted by long boiling.

(3.) The unequal absorption by wool of the basic hydrates and dissociated acids, and its reactions upon each of them, cause these differences.

(4.) The excess of salt, it would appear, may be replaced by small quantities of acids, or of acid salts of potassium (bisulphate, binoxalate, tartar, &c.), which in water are resolved into free acid and neutral salt.

(5.) The augmentation of the metallic hydrate fixed is procured by addition of water, increase of heat, or prolonged contact.

(6.) The colour which pure wool takes in dyeing, confuses that due to the first portion of hydrated acid, or metallic hydrate absorbed by the wool. Acids act specially in purifying wool: they seem also to set the colouring matters free from glucosides. The metallic hydrates fix coloured lakes upon wool in a different manner.

## B. CHROME-ALUM WITH VARIOUS ACIDS.

### 1. Chrome-Alum and Sulphuric Acid.

The foregoing series of experiments have shown that although the dissociation of chrome-alum may be prevented by employing large amounts, still level dyeing with the use of this mordant is not to be obtained in this manner, and hence experiments were now tried with the addition of acids.

**Experiment 15.**—Wool was mordanted with 10 per cent. chrome-alum + 0, 1, 2, 3, 4 mols.  $\text{H}_2\text{SO}_4$ .

In baths Nos. 1 and 2 strong dissociation occurred, in No. 3 there was much less, but in Nos. 4 and 5 the solutions remained perfectly clear; the waste liquor of No. 1 appeared almost colourless, but the rest showed a green coloration, which gradually became more intense towards No. 5. Nevertheless the dyed patterns showed that from Nos. 2-5 the amount of chromium fixed gradually increased, Nos. 4 and 5 especially giving dark colours.

Here, too, however, a microscopic examination showed very unequal dyeing of the different fibres, and the patterns themselves had a "seedy" appearance, just as when large percentages of chrome-alum were employed. In individual fibres the tips always appeared darker than the roots, i.e., the younger part of the fibre. The same observations were made in the case of unspun lamb's wool secured in the laboratory, which was tried perchance the woollen cashmeres employed contained more than one quality of wool. Here, too, the use of bichromate of potash gave level colours, the irregularities only appearing with the employment of the chrome oxide salt. The difference in the general behaviour of cotton and wool towards mordants is here shown in a striking manner. With the former, as is well known, we have to employ basic salts; whereas with the latter the presence of free acid seems to be absolutely essential.

The amounts of sulphuric acid recommended many years ago by Peissert were 1.66-2.5 mols. per 1 mol. chrome-alum. When dyed in alizarin, pattern No. 5 gave indeed a very deep bluish Bordeaux, but the colour was not full and it had a peculiar greyish hue, and differed entirely from the normal Bordeaux obtained from alizarin.

No chromium determinations were made, but the titration of the waste liquor of bath No. 5 showed an absorption by the wool of 0.288 grm.  $\text{SO}_3 = 0.3528$  grm.  $\text{H}_2\text{SO}_4$ , so that the mordant fixed upon it was very acid.

The poor result as regards colour here obtained accords entirely with that obtained some years ago by Liechti and Schwitzer, when it was shown that the use of sulphuric acid as an assistant cannot replace organic acids (*Mittheilungen des technologischen Gewerbe-Museums, Wien, III., p. 56*).

### 2. Chrome-Alum and Acetic Acid.

If acetic acid proved to have the power of preventing the dissociation of the chrome-alum, good results in dyeing might be expected, but experiment showed this not to be the case.

**Experiment 16.**—Wool was mordanted with 10 per cent. chrome-alum, + 0, 3, 6, 8, 10, 12, 14 mols. acetic acid, also + 2, 4, 6 mols. sodium acetate. Baths Nos. 8, 9, 10 became turbid first; after 35 minutes, baths Nos. 2, 3, 4 became also turbid, but more slightly; at 95° C. bath No. 5 became turbid, but to a still smaller extent; while baths Nos. 6 and 7 remained clear. When washed and dyed with 25 per cent. logwood, poor, "seedy" greys only were obtained, little calculated to inspire further experiment in this direction. A note of Havrez gave hope that better results might be obtainable by mordanting at a lower temperature. The experiment was therefore repeated, employing the amounts of Nos. 2-7 and a temperature of 60-70° C. In this case all the baths remained clear, but although the dissociation of the chrome-alum had thus been prevented, the dyed result was even worse than before. When microscopically examined some of the fibres showed a deep bluish grey colour, but others were almost colourless.

This result appears to indicate that a more acid compound than  $\text{R}_2(\text{SO}_4)_3$  must necessarily be present on the fibre in order to produce the colour lake within its substance; acetic acid being a volatile acid, is apparently not adapted for this purpose.

The last three mordants, Nos. 8, 9, 10, with sodium acetate, were included in order to see if a salt less rich in  $\text{SO}_4$  than chrome-alum could be fixed upon the wool, but, as expected, the results were very poor. Already in 1886 Liechti and Schwitzer found that pure chromium acetate gave unfavourable results when employed as a mordant for wool.

Before referring to further mordanting experiments, it is necessary to cite briefly a few experiments made with the view of determining the importance or otherwise of certain possible sources of error. As is well known to the analytical chemist, certain kinds of glass are not wholly unattacked by boiling water, and there was a possibility, therefore, that the chrome-alum might be to a certain extent decomposed by the glass. One of the glass dye-vessels containing 600 cc. water was, therefore, heated in the course of an hour to the boiling-point and boiled one hour, with the addition of a little methyl orange, just reddened with a trace of hydro-

chloric acid, and afterwards allowed to cool. On comparing the tinted water which had been boiled with a small sample of it which had been set aside previously, no indications of any neutralisation could be seen. Another similar experiment was made by boiling 600 cc. water with the addition of an amount of sulphuric acid (6 cc. normal  $H_2SO_4$ ) equivalent to 1 gm. chrome-alum; to neutralise the liquid afterwards 6 cc. normal NaOH was required, so that here, too, it was shown that the alkali of the glass dye-vessel had exercised no action in the mordanting experiments.

Another possible source of error might of course be the faint alkalinity of the Leeds water, as well as that of the wool itself, due to the scouring process. For 600 cc. Leeds water there was required 0.21 cc. normal acid to neutralise it, and for the 10 grms. wool, 0.79 cc.; therefore together 1 cc. acid. A sample of 10 grms. wool was therefore mordanted with 10 per cent. chrome-alum in 600 cc. water, with the addition of 1 cc. normal sulphuric acid, but the same appearances as those already described were again observed. It is therefore, as we believe, conclusively proved that the decomposition of the chrome-alum is brought about by the wool itself absorbing the sulphuric acid from the dissociated chrome-alum in the mordanting bath.

**Experiment 17.**—It seemed possible to prevent the decomposition of the chrome-alum, if the wool's affinity for acid were satisfied *before* the mordanting process. To this end two samples of wool were boiled for  $1\frac{1}{2}$  hours with 600 cc., the one with the addition of 1 gm. sulphuric acid, and the other with its equivalent, 1.88 grms. cream of tartar. After washing, the samples were mordanted as usual in a separate bath with 10 per cent. chrome-alum. Even here, however, though to a less extent, turbidity and decomposition of the chrome-alum ensued. On dyeing with logwood better bluish-black colours were obtained than with the use of chrome-alum alone, but they were not altogether satisfactory either in colour or evenness. Examination by the microscope showed both deep black and pale bluish slate-coloured fibres. On titrating the waste liquors it was found that an absorption of 0.2832 gm.  $SO_3$  and cream of tartar corresponding to 0.1276 gm.  $SO_3$  had occurred, so that the amount of the latter substance absorbed by the wool was 45 per cent. of the former.

**Experiment 18.**—A special experiment showed that "chlorinated" wool may be well mordanted with chrome-alum without any decomposition being noticeable in the bath. A 10-grm. sample of ordinary wool was heated with 600 cc. water and 2 grms. sulphuric acid, then well squeezed and mordanted with 10 per cent. chrome-alum, and in this case no decomposition in the mordant bath was noticeable.

If after the treatment with acid the wool is steeped for a quarter of an hour in a cold dilute solution of bleaching powder, then washed and mordanted with chrome alum, no decomposition of the chrome-alum occurs in the bath, but one observes an interesting formation of chromic acid.

Apart from the effect of the oxidation of the wool, possibly the good results obtained on "chlorinated" wool, with some colouring matters at least, may depend to some extent upon the acid absorbed by the wool. In the case of the above two samples, when dyed with alizarin, the non-chlorinated sample gave a garnet-red colour, pointing evidently to the effect of the acid, absorbed by the wool, whereas the second one gave a bluish Bordeaux colour, which probably contained lime.

It has already been stated that the wool takes up the free sulphuric acid from the dissociated green chrome alum solution, with the formation and precipitation in the bath and on the wool of the basic compound—

and it has been shown that the same reaction takes place to a less extent even in the cold, if the operation is prolonged sufficiently, hence the idea occurs to one that even in the case of the violet chrome-alum solution, there may be a partial or incipient dissociation.

Here the first question to be determined is whether or not free sulphuric acid is present upon wool mordanted with chrome-alum.

**Experiment 19.**—A piece of chrome-alum mordanted wool was divided into six parts, which was then dyed with logwood—

- |      |   |
|------|---|
| (1.) | Without addition.                             |
| (2.) | With addition of 1 cc. normal sulphuric acid. |
| (3.) | " " 1 " " oxalic acid.                        |
| (4.) | " " 1 " " tartaric acid.                      |
| (5.) | " " 1 " " sodium acetate.                     |
| (6.) | " " 1 " " calcium acetate.                    |

The colours were of course poor, "seely," brownish-greys, and even with the naked eye one could detect among the black fibres dirty pale brown ones. The patterns Nos. 2—4 had more of a reddish-brown cast, so that the colour was certainly not improved by an addition of acid to the dye-bath. This result accorded entirely with the negative one of another experiment, in which the attempt was made to correct an already decomposed chrome-alum bath. Patterns Nos. 5 and 6 showed plainly the beneficial effect of neutralising the free sulphuric acid in the wool by the sodium or calcium acetate, the latter seeming indeed better than the former. The colours of these patterns were dark bluish-greys, but even here the microscope revealed almost colourless fibres alongside of others which were deep blue.

Why individual wool fibres should behave so differently, as is here shown, is a moot point; whether it is due to a mixture of wool or whether the mature fibres behave differently to those of more recent growth, with respect to their power of absorption of the mordant constituents, is not yet determined. It always appeared, however, as if the coarser fibres had a deeper colour than the thinner ones. In any case it is very striking that similar marked differences are never met with in wool mordanted with bichromate of potash, and explains to some extent the preference of practical dyers for this mordant. O. N. Witt has also referred to this matter in connection with the dyeing of wool with indulin, and dyers meet with it frequently in ordinary practice; it is certainly one of considerable importance, and there is no doubt that in many cases in practice irregular colours have been caused by the spinner rather than by the dyer.

The different behaviour of various qualities of wool towards many colouring matters is often met with, especially in the case of azo-colours, and when two or three colours are being applied simultaneously. Sometimes, at a given temperature, one colour is already entirely taken up from the dye-bath while the others have been scarcely attracted at all, but only certain parts of the mixture of wools had become dyed, the others dyeing afterwards at higher temperatures, the end result being that the dyed wool contains fibres of different colours, and the general colour is bad because of the irrational mixing of different qualities of wool.

This is not the time to enter into this question further, but it seems possible that here, too, the unequal attraction for acid by the different wool fibres lies at the root of the matter. The observation of Breinl that wool treated with dilute sulphuric acid and then steamed, dyes deeper colours than untreated wool, is explained most simply by ascribing it to the absorption of acid.

**Experiment 20.**—Another method of showing the presence of absorbed free acid may be based upon the behaviours of the acid azo colours. Wool, after mordanting with chrome-alum and washing, was dyed with 3 per cent. Fast Red E (BASAR). The bath was almost completely exhausted, and the wool was dyed a deep red; the shade was, of course, considerably dulled by the presence on the fibre of the basic chromic sulphate, but otherwise the dye was quite normal. A microscopic examination revealed no undyed fibres, but there were all shades from pale to dark red. The waste dye liquor had a neutral reaction. Unmordanted wool dyed in a similar manner only acquired a pale flesh tint.

**Experiment 21.**—Two samples of wool, 10 grms. each, were dyed simultaneously with 600 cc. distilled water, 0.3 gm. Fast Red E, the one with addition of 6 cc. normal sulphuric acid, the other with 1 gm. chrome-alum. The one with sulphuric acid exhausted the bath completely; the

chrome-alum bath became gradually turbid and was not fully exhausted; the colour of the wool was of course duller, of a bluer red, and not so deep as the other. The paler colour is explained by the fact that a portion of the  $\text{SO}_3$  could not assist in developing the Fast Red, since it was present in the precipitated basic chromic sulphate. Taking this into account, to have had equal amounts of sulphuric acid in action, one ought to have employed 1.28 grms. chrome-alum. For the rest, 6 cc. normal sulphuric acid are equivalent only to 0.83 grm.  $\text{NaHSO}_4$ , of which usually 10 per cent. is recommended to be used with acid colours, *i.e.*, 1 grm. in the present instance. The basic chromic sulphate precipitated in the bath had not attracted any colouring matter. Here, too, the dyeing shows clearly the absorption of sulphuric acid from the chrome-alum by the wool.

**Experiment 22.**—This is to some extent a repetition of experiment 21 (employing an equivalent amount of chromium oxalate instead of the sulphate), with the object of preventing the formation of a precipitate. By chance Bordeaux S was used instead of Fast Red. The bath remained clear, but was only about two-thirds exhausted. On addition of  $\text{NaOH}$  to the waste liquor, pure chromic hydrate was precipitated. It would appear from this result that wool has a greater attraction for sulphuric acid than for oxalic acid from chromium salts.

The experiments already referred to point to the necessity of determining the behaviour of wool towards various acids before continuing the study of the use of chrome-alum with the addition of organic acids. Such experiments were not originally intended when planning the work, but the interesting behaviour of wool towards chrome-alum seemed to compel this step, although, perhaps, little new could be expected from it.

In the first instance it seemed interesting to determine whether a relation exists between the amounts of acid absorbed respectively from a chrome-alum bath and one of free sulphuric acid. Should this be the case it would be an excellent proof that the decomposition of the chrome-alum is a direct result of the absorption of the sulphuric acid by the wool. Here, too, the experiments were always conducted in such a manner that 10 grms. wool were boiled for  $\frac{1}{2}$  hours with 600 cc. water containing the acids selected. After allowing the baths to cool and making up to the original volume, a definite portion was titrated and calculated for 600 cc.; the deficiency of acid was considered to have been absorbed by the wool. In this manner alone comparable results are to be expected, since it is practically impossible to wash out equally different samples of wool boiled with different acids, since the latter appear to be retained by the wool in different proportions. With respect to cream of tartar, amounts were always taken in which the free acid was equivalent to the other acids. According to Roard and Thenard, namely, wool decomposes cream of tartar into free tartaric acid which is absorbed by the wool and neutral potassium tartrate which remains in the bath. Kuhlmann, too, states that it is only the free tartaric acid which is active, and hence recommends that dyers should invariably liberate the whole of the tartaric acid by an addition of sulphuric acid. It may be incidentally mentioned that in all the waste acid liquors the presence of ammonia could be detected.

The early experiments on this subject of the absorption of acids by fibre, seem to be absolutely worthless for our present purpose, because they were made under conditions absolutely different from those imposed in practice, *e.g.*, those of Chevreul (1833) and Bolley (1859), as well as of Mills and Takamine (Journ. Soc. Chem. Industry, March 1883). More important for us are the recent experiments and analyses of Knecht (Journ. Soc. Dyers and Colourists, 4, 104). He found that wool boiled with 5 per cent. sulphuric acid, absorbed 3.6 per cent.; by subsequently extracting the fibre three times with boiling water 1.26 per cent. could be removed, so that 2.34 per cent. was permanently absorbed or neutralised by the wool. The amount of other acids equivalent to this would be 3 per cent. oxalic acid, 3.6 per cent. tartaric acid, 8.98 per cent. cream of tartar, 7.54 per cent. potash-alum, 7.94 per cent. chrome-alum. Now, according to Knecht, wool boiled

with 10 per cent. tartar absorbs 4.28 per cent. which corresponds to 1.111 grms.  $\text{H}_2\text{SO}_4$ , *i.e.*, only 17.5 per cent. of the above 2.34 per cent. With the use of only 5 per cent. alum (1.55 per cent.  $\text{H}_2\text{SO}_4$ ) total absorption of the sulphuric acid occurred; the more alum used the less relatively is the amount of sulphuric acid absorbed, as already previously observed by Havrez, and later by us in the case of chrome-alum. With the use of 20 per cent., 15 per cent., 10 per cent. alum, the amounts of  $\text{SO}_3$  found by Knecht to be absorbed were 11.0 per cent., 14.6 per cent., 22.1 per cent. of the 25.42 per cent.  $\text{SO}_3$  theoretically present. The cause of this is ascribed by him to dissociation. With 15 per cent. alum there was 7.1 per cent.  $\text{SO}_3$  permanently absorbed or neutralised, and there is probably fixed on the wool a basic sulphate. If the mordanted wool was not extracted with boiling distilled water there was found to be absorbed 14.60 per cent.  $\text{SO}_3$  instead of 7.1 per cent. From Knecht's data we cannot draw the same conclusions exactly, no doubt because in these cases titration does not suffice to give one a clear insight into the matter, and one ought so to titrate as to determine in an acid bath first the free acid and then that combined with the alumina.

Knecht presented to the wool—

$\text{Al}_2\text{O}_3$ , 0.0807 grm., and  $\text{SO}_3$ , 0.1898 grm.;

there remained in the bath—

$\text{Al}_2\text{O}_3$ , 0.0355 grm., and  $\text{SO}_3$ , 0.1367 grm.;

there was therefore on the wool—

$\text{Al}_2\text{O}_3$ , 0.0452 grm., and  $\text{SO}_3$ , 0.0531 grm.

From these data one may calculate as follows:—

$$0.0452 : 0.0531 = 102 : x; x = 119 \text{ and } \frac{119}{80} = 1.487$$

that is to say, the wool eventually contains the basic aluminium sulphate ( $\text{Al}_2\text{O}_3 : 1.487 \text{ SO}_3$ ), and if calculated in the same manner the bath is shown to contain—

If Knecht's data respecting the temporarily fixed compound are calculated in a similar way, the conclusion arrived at is that both on the wool and in the waste mordant liquor there is present ( $\text{Al}_2\text{O}_3 : 3\text{SO}_3$ ), this is—

Presented to wool—

$\text{Al}_2\text{O}_3$ , 0.0807 grm., and  $\text{SO}_3$ , 0.1898 grm.;

in the bath—

$\text{Al}_2\text{O}_3$ , 0.0355 grm. (?), and  $\text{SO}_3$ , 0.0837 grm.;

therefore on the wool—

$\text{Al}_2\text{O}_3$ , 0.0452 grm. (?), and  $\text{SO}_3$ , 0.1061 grm.

In both cases the figures work out to ( $\text{Al}_2\text{O}_3 : 3\text{SO}_3$ ).

According to the amount of alum employed in mordanting, as well as that of the water and the duration of the boiling, different results are obtained, and it is impossible, therefore, to give exact formulae which are generally applicable. The dissociation becomes less the larger the amounts of alum employed, and seems to us to become nil with the use of 35 per cent. chrome-alum. Knecht found that with increasing amounts of acid or alum, proportionally diminishing amounts are fixed, *e.g.*, 1.13 per cent. with addition of 20 per cent.  $\text{H}_2\text{SO}_4$ , and only 4.82 per cent. with 40 per cent.  $\text{H}_2\text{SO}_4$ .

In the case of alum no further decomposition will of course occur after the wool's need for acid has been satisfied. With the use of sufficiently large amounts of alum the baths must therefore remain clear, since only a very faintly basic sulphate is formed.

Knecht does not seem to have observed the actual formation in the solution of insoluble basic sulphate, although it is somewhat striking (especially in the case of chrome-alum). His conclusions on the question are as follows:—

"When boiled with 15 per cent. alum, wool elects a partial decomposition of the salt, leaving free acid in solution. The amount of the latter is, however, very small. The  $\text{Al}_2\text{O}_3$  and  $\text{SO}_3$  appear to be absorbed in about equivalent proportions."

#### Absorption of Various Acids by Wool.

In all these experiments it was found impossible to obtain concordant results. The results varied, for example, according to the amount of acid presented to the fibre, as noticed

also by Knecht, although we never employed such large amounts of acid as he. They varied, too, according to the concentration of the baths.

It is well perhaps to refer here to the difficulties connected with the equal heating and evaporation of the several racks, although every precaution was taken. To avoid gross errors, the baths were maintained at a constant level, and, after cooling thoroughly, were again made up to the mark (600 cc.) with water, and well stirred with the wool some time until a state of equilibrium had been established, before taking a portion of the liquid for analysis.

#### Absorption of Sulphuric Acid.

*Experiment 23.*—(1.) When 10 cc. normal  $\text{H}_2\text{SO}_4$  were used, i.e., 0.49 gm.  $\text{H}_2\text{SO}_4 = 0.40$  gm.  $\text{SO}_3$ , the following amounts were absorbed:—

$\text{H}_2\text{SO}_4$		$\text{SO}_3$
Grm.		Grm.
0.3467	=	0.283
0.3325	=	0.287
0.3469	=	0.283
0.3136	=	0.256
0.3386	=	0.276
0.2640	=	0.240
0.3332	=	0.272
Average 0.332	=	0.271

(2.) When 6 cc. normal  $\text{H}_2\text{SO}_4$  were used, i.e., 0.294 gm.  $\text{H}_2\text{SO}_4 = 0.240$  gm.  $\text{SO}_3$ , and equivalent to 1 gm. chrome-alum, the following amounts were absorbed:—

$\text{H}_2\text{SO}_4$		$\text{SO}_3$
Grm.		Grm.
0.25382	=	0.2072
0.24696	=	0.2016
0.2400	=	0.2000
Average 0.2439	=	0.2029

The above 10 determinations, made at different times, show therefore that a reduction in the amount of acid presented to the wool from 10 cc. to 6 cc. causes the fibre to absorb less acid, in the proportion of 100:74.3.

To determine the influence of the concentration of the liquid, three amounts of solution were employed, viz.: (a) 333 cc., (b) 666 cc., (c) 1,000 cc., each containing 10 cc. normal  $\text{H}_2\text{SO}_4$ . The amounts of  $\text{H}_2\text{SO}_4$  absorbed by the wool were 0.31605, 0.30331, and 0.27881 gm. respectively; that is, with increasing concentration the amounts absorbed had the ratio 100:108:113. Simultaneous with the last three determinations, the behaviour of wool towards hydrochloric and nitric acids was examined, 10 cc. of the normal acids being employed in each case in 666 cc. water. The amounts absorbed, expressed in terms of  $\text{H}_2\text{SO}_4$ , are as follows:—

For  $\text{HCl}$ , 0.2793 gm.; for  $\text{HNO}_3$ , 0.28175 gm.; that is a little less than in the case of  $\text{H}_2\text{SO}_4$ , a deviation which is possibly due to the volatility of these acids.

Parallel experiments boiling wool with 1 gm. chrome-alum and 6 cc. normal  $\text{H}_2\text{SO}_4$  respectively, i.e., equal amounts of  $\text{SO}_3$ , gave the following amounts of  $\text{H}_2\text{SO}_4$  or  $\text{SO}_3$  absorbed:—

#### For chrome-alum—

- (a.) 0.24696 gm.  $\text{H}_2\text{SO}_4 = 0.2016$  gm.  $\text{SO}_3$ , equiv. to 0.8400 gm. chrome-alum.
- (b.) 0.26068 gm.  $\text{H}_2\text{SO}_4 = 0.2128$  gm.  $\text{SO}_3$ , equiv. to 0.8866 gm. chrome-alum.
- (c.) 0.25676 gm.  $\text{H}_2\text{SO}_4 = 0.2096$  gm.  $\text{SO}_3$ , equiv. to 0.8733 gm. chrome-alum.
- (d.) 0.24813 gm.  $\text{H}_2\text{SO}_4 = 0.2028$  gm.  $\text{SO}_3$ , equiv. to 0.8459 gm. chrome-alum.

#### For sulphuric acid—

- (a.) 0.25382 gm.  $\text{H}_2\text{SO}_4 = 0.2072$  gm.  $\text{SO}_3$ , equiv. to 0.8630 gm. chrome-alum.
- (b.) 0.24696 gm.  $\text{H}_2\text{SO}_4 = 0.2016$  gm.  $\text{SO}_3$ , equiv. to 0.8566 gm. chrome-alum.

These figures are sufficiently concordant to show that the decomposition of the chrome-alum by the wool is really due to the absorption of acid by the fibre.

As previously stated, this decomposition also takes place to a small extent even in the cold, and in accordance with this fact it was found that 10 grms. wool steeped for a month in 600 cc. water containing 10 cc. normal  $\text{H}_2\text{SO}_4$ , absorbed 0.28837 gm.  $\text{H}_2\text{SO}_4$ , equivalent to 0.235 gm.  $\text{SO}_3$ .

We are inclined to share Knecht's view, as expressed in his conclusions, viz., that the acid is not combined permanently with the wool, although it is certainly very difficult to remove the last traces of acid from the fibre. A sample of wool boiled with a solution (600 cc.) containing 10 cc. normal  $\text{H}_2\text{SO}_4$  absorbed 0.3136. When the squeezed wool was extracted as completely as possible with water, and this was neutralised with normal  $\text{NaOH}$ , the wool still lying in the liquid, the latter invariably became acid again after some time, but by neutralising again and again after similar rests, it was possible to show the presence in the liquid of the full amount of acid originally employed. In another repetition experiment, the wool, having absorbed 0.31684 gm.  $\text{H}_2\text{SO}_4$ , was boiled with water for two hours; the liquid was then neutralised with normal  $\text{NaOH}$ , and the operations were repeated till no further quantity of sulphuric acid could be extracted; here all the sulphuric acid absorbed could be accounted for. Indeed in both cases a little more than 10 cc. normal  $\text{NaOH}$  was required, it is namely very difficult to titrate with exactitude in protracted and intermittent operations such as those above, and during the intervening time the indicators may have altered slightly.

#### Absorption of Organic Acids and Cream of Tartar.

The following acids, &c. were compared with each other, and the amounts absorbed by the wool are expressed in terms of sulphuric acid ( $\text{H}_2\text{SO}_4$ ):—

- 10 cc. normal sulphuric acid gave up 0.3386 gm.
- 10 cc. normal oxalic acid gave up 0.3258 gm.
- 10 cc. normal tartaric acid gave up 0.2964 gm.
- 1.88 grms. cream of tartar gave up 0.1536 gm.

Whereas, therefore, oxalic, tartaric, and sulphuric acids are absorbed by the wool in almost equivalent amounts, cream of tartar gives up very much less, namely, 45.4 per cent. only of the amount absorbed from sulphuric acid, this being the mean of five determinations.

In concluding this part of our communication, we venture to say that it is evident from the above-cited experiments that the behaviour of the wool fibre towards metallic salt solutions is very different from that of the cotton fibre.

In the case of cotton mordanted with metallic salts, we understand the fibre to be charged with hydrates or insoluble basic salts, and the mode of mordanting cotton is adapted to the precipitation of these, the fibre merely acting the part of a carrier. With wool it is different; basic salts may certainly be readily precipitated, but the wool thus mordanted gives poor results when dyed. How is this? We hope to deal with this question in our next communication. Meanwhile, it seems evident that the comparative instability of the wool under the ordinary conditions of mordanting imposed, its amide character, the liberation of ammonia, and its strong absorptive power for acids, each play their part in the mordanting process with metallic salts.

(To be continued.)

### SESSION 1893-94.

Glasgow:—

May 1st.—Prof. E. J. Mills and Mr. Saweys. "On the Action of Alkalis on Gelatin."

Edinburgh:—

April 10th.—Dr. J. B. Readman. "The Effect of the Saline Constituents of Water on the Character of Beer."

Meeting held in the Philosophical Society's Rooms, 207, Bath Street, Glasgow, on Tuesday, March 6th, 1894.

PROF. E. J. MILLS, F.R.S., IN THE CHAIR.

## THE PRODUCTION OF GAS FROM PARAFFIN OILS, AND FROM PURE MEMBERS OF PARAFFIN AND TERPENE SERIES.

BY JAMES F. TOCHER, F.I.C., F.C.S.

THE production of gas from oil, which is receiving special attention at the present time, was first undertaken in 1815, and was carried on successfully for some time, when it was superseded by coal-gas. In 1876 its manufacture was resuscitated for the purpose of lighting railway carriages, and since that time it has been continuously used, not only in the illumination of carriages, but also of lighthouses and buoys. The various forms for the decomposition of the oils were described by Professor Armstrong in his paper on the "Manufacture of Gas from Oil," read before this Society in 1884.

Within the last few years oil-gas has excited the widest interest, owing to its being adopted as an enricher of coal-gas. Two years ago the subject was brought under my notice by Mr. John Mackay, late manager of the Peterhead works, who read a short paper on "Enriching Coal-Gas by Paraffin Oils" at the annual meeting of the North British Association of Gas Managers held at Stirling in July 1892. Owing to the increased price of candles, Mr. Mackay, in common with many others, tried the utility of oil as an enricher. It being undesirable to erect any special plant, he utilized the ordinary  $\square$ -shaped fire-clay retorts, and passed the oil into the empty retort in the form of a spray by injection at high pressure. His results, given in the paper above referred to, justified the trial he had made, but as the oil was decomposed at a far higher temperature than that employed by the Pintsch and other special processes, and gave different results, an investigation into the conditions under which the various oils could be destructively distilled to advantage was suggested to me.

The earliest experiments in oil-gas making were conducted either in narrow tubes or in retorts filled with coke or iron filings, thereby giving a large heated surface in proportion to cubical capacity, and resulted in the production of much tar and little gas.

Dr. Stevenson Macphail's experiments (1872) were conducted in retorts filled with coke, while Lotz (1877) experimented with a tube 4 ft. long and 2 in. diameter. Lieberman and Burg (1878) used tubes 1 m. long and 1 in. diameter, and found that the yield of gas was greater when the tube was empty than when filled with charcoal. Professor Lewis, in his paper on "The Production of Oil-gas from Russian Petroleum" (this Journal, 1892, 584-586), gave the results of cracking petroleum in retorts of various sizes which show the greatest sperm value in using retorts where the surface is small in proportion to the cubical capacity. In carrying out the following experiments three retorts were used:—(1) 36 in.  $\times$  6 in.; (2) 36 in.  $\times$  5 in.; (3) 8 in.  $\times$  3 in., where  $\frac{\text{surface}}{\text{capacity}}$  = 8.6, 10.3, and 14.1 sq. ft. surface per cubic foot respectively. A  $\square$  clay retort was also used, in which the ratio was 3.75. In giving results from these, I shall also compare, in the latter part of the paper, various retorts in use, showing how far the different ratios of surface and capacity, &c., affect the cracking up of oils.

The retorts were set in the furnace with a fall 4 ft. The mouths of the two larger ones were closed by iron plates, which were secured by bolts. A stopcock was placed in the centre of each plate, which served the double purpose of determining the temperature and noting the colour of the gas during decomposition of the oil. The oil was fed into retort by means of a pipe inserted with a bend to upper end of retort, and led to within 2 in. of the lower end, where a small flat sheet of iron was placed in order to provide for the proper dispersion of the oil dropping from the pipe. The gas was passed from upper retort into a small cylindrical vessel, where the residuals were collected (and which was utilised to return residuals to retort in determining the ultimate sperm value of 0.884 oils), thence through small purifier and meter to small holder. The gases from other retorts were passed through separate vessels for collection of residuals and thence to holders. With the exception of fire-clay retort, the temperatures were determined by means of Siemen's water pyrometer, the point selected in the retort being the top of iron plate, on which the oil dropped. The temperature of fire-clay retort was about 1,200° C., or bright orange, that degree being usually employed in the manufacture of coal-gas.

The illuminating power was determined in the usual way, with the exception that suitable burners were selected and the rate adjusted to suit the quality of each gas, the results being then calculated to 5 cubic feet of gas and 120 grains sperm per hour. Each gas was analysed prior to determination of candle power:  $\text{CO}_2$  by  $\text{KOH}$  sol., O by alkaline pyrogallol, olefines, &c., by  $\text{Br}$  (br vapour removed by  $\text{KOH}$ ), and CO by cuprous chloride. A portion of the residual gas was mixed with excess of O and exploded,  $\text{CH}_4$ , H (and N) being estimated after explosion in the usual way. The carbon and hydrogen densities, when such are given, were determined by exploding a portion of the original gas in excess of oxygen and calculating the densities from the following formulae, where—

A =  $\text{CO}_2$  in 100 vols. of gas.

B =  $\text{CO}_2$ , due to  $\text{CH}_4$  (CO and  $\text{CO}_2$  if present) in 100 vols. of gas.

a = O required for complete combustion of 100 vols. of gas.

$\beta$  = O required for combustion of H,  $\text{CH}_4$ , and C of  $\text{C}_n\text{H}_m$  hydrocarbons.

C = Percentage of  $\text{C}_n\text{H}_m$  hydrocarbons in 100 vols. of gas.

$$(1) \frac{A - B}{C} = \text{carbon density:}$$

$$(2) \frac{a - \beta}{C} = \text{hydrogen density:}$$

*Paraffin Oils.*

The first series of experiments were conducted in retort 6 in. × 6 in., with the following grades of paraffin oils,

viz.:—(1) Mineral naphtha, sp. gr. 0.730; (2) burning oil, sp. gr. 0.807; (3) light mineral oil, sp. gr. 0.847; and (4) heavy mineral oil, sp. gr. 0.884. The following results were obtained:—

An uniform rate of flow was maintained throughout, and was, as nearly as possible, the same in all these experiments. On taking the temperature of the retort from time to time, after decomposition of the oil had been effected, it was found to have fallen on an average 50°–100° C.

The results obtained in decomposing the naphtha at 600° and 800° are similar so far as the composition and candle-power of the gas are concerned, but at 600° the yield was less, giving a smaller sperm value, while the percentage of residuals was double that found at 800° C.

The burning oil at 600° C. gave only 75 cubic feet of 48.7 candle-gas, but on raising the temperature to 800° C. a yield of 93 cubic feet of 61.4-candle gas was obtained. The unsaturated hydrocarbons in the gas had increased by 10.3 per cent., while the volume of residuals had decreased by one-third.

A comparison of the results from 0.847 oil show that any degree of temperature much above 800°–900° C. reduces the sperm value of the gas. At 600° C., 64 cubic feet of 52.5-candle gas were obtained, equal to 659 candles per gallon; at 800° C. a yield of 82 cubic feet of 64.8-candle gas was obtained, equal to 1,062 candles per gallon, while on decomposing the oil in a fire-clay retort at 1,100°–1,200° C. (bright orange), the yield rose to 95 cubic feet, the candle-power being 36.2, equal to 688 candles per gallon, a figure similar to that obtained at 600° C. The percentage of hydrogen in the gas was double that found at 800° C., while the unsaturated hydrocarbons were reduced to less than one-half, showing that a highly heated surface tends to the production of free hydrogen at the expense of the heavier hydrocarbons.

The first experiment with 0.884 oil was performed at a temperature approaching 500° C. The yield was small, only 34 cubic feet per gallon, while the percentage of residuals amounted to 62.3 per cent. The candle-power was high, viz., 63.8, and the gas contained 44.7 per cent. of heavy hydrocarbons with a carbon density of 3.11. At 600° C. the yield rose to 59 cubic feet per gallon, while the

candle-power fell to 57.7, and the residuals to 41.5 per cent. A yield of 108 cubic feet of 49-candle gas was obtained at 850° C., equal to 1,058 candles per gallon. The residuals amounted only to 9.4 per cent.

The tar obtained from the decomposition of naphtha at 800° C. was fractionally distilled, 35.1 per cent. distilling over between 70°–100° C., while 39 per cent. of the naphtha itself distilled over between 60°–100° C.; burning oil-tar gave 23 per cent. up to 100° C., 0.847 oil-tar at 800° C. gave 13.5 per cent., 0.884 oil-tar at 600° C. gave 1.1, and 6 per cent. at 850° C.; while nothing was obtained from 0.847 oil-tar at 1,100° C. until 190°–200° C.

From the results given in Table I., it is apparent that by the method of decomposition employed, the degree of temperature giving the highest sperm value ranges from 800°–850° C. In the Pintsch, Patterson, and Keith retorts, where the method of cracking the oil is similar in principle to that employed in these experiments, the temperature is higher, viz., 900°–1,000° C., while the sperm values obtained are lower. It is clear that if a temperature lower than 800° C. was adopted in practice, the conditions under which the oil is to be decomposed must be entirely different. It is the special feature of the new process of manufacturing oil-gas patented by Messrs. Young and Bell last year that a low temperature is employed, while the residuals (which we have seen from results at 600° C. amount to over 60 per cent.) are run back into retort to be decomposed. The actual temperature employed is, I believe, lower than 600° C., and therefore a larger volume of material must pass over unchanged—at least ungasified, but as it is returned to retort, the whole of the material is utilised, with the result that there are no liquid residuals, but instead, a solid residue is left in retort.

The following experiment, undertaken to ascertain the sperm value obtainable when a sample of oil is wholly converted into gas and solid residue, has also afforded an opportunity of expressing the decomposition of the oil in clearer terms. The cylindrical vessel, which in the previous

experiments served also as a washer, was utilised. A small pipe was fixed to lower edge of vessel and carried to a point about an inch above funnel through which the oil was introduced to retort. Eight pounds of 0.884 mineral oil were placed in the vessel. The retort being heated to about 600° C., oil was allowed to pass into retort by opening stopcock attached to end of pipe. No fresh oil was introduced; the oil, mixed with tar formed, being simply allowed to flow into retort at slow rate until the whole was converted into gas and solid residue. The candle-power of the first portion of the gas was 66.1, while that of the final portion was 51.5. The specific gravity of the oil, taken three times during the course of the experiment, was successively 0.889, 0.881, and 0.895. A yield of 81 cubic feet of 61.1-candle gas was obtained, equal to 1,094 candles per gallon, or 131,280 grains sperm per gallon. This may be conveniently termed the ultimate sperm value, seeing that it is the highest attainable figure in experimentally converting the whole of the oil into gas and carbon. There was a solid residue of 24.9 per cent.; the percentage composition of the gas was as follows:—

	Per Cent.
CnHm hydrocarbons .....	42.9
CnHn+2 .....	43.5
Hydrogen .....	13.3

Carbon density = 2.89, hydrogen density = 5.12. In order to trace out the decomposition of the oil, the percentages of carbon and hydrogen present in the oil were determined by combustion. The following is the mean of two determinations:—

	Per Cent.
Carbon .....	86.68
Hydrogen .....	11.67

The average molecular weight of the substances of which the oil is composed, was determined by noting the depression of the freezing point of benzene. Two determinations were made, the figures being 318 and 322. The average formula for the oil is therefore represented by  $C_{24}H_{38}$ . On converting the results obtained from cracking up the oil into per cent. by weight of oil taken, the following figures are obtained:—Hydrogen 0.7, methane 19.8, CnHm 50.7, carbon 24.9, and loss 3.9. The decomposition of the oil is therefore expressed by the following:—

	Theory.	Found.
	Per Cent.	Per Cent.
H <sub>2</sub> .....	0.6	0.7
4CH <sub>4</sub> .....	19.6	19.8
4(C <sub>3</sub> H <sub>8</sub> ) .....	50.3	50.7
4C <sub>2</sub> .....	29.5	24.9
Loss .....	..	3.9
	100.0	100.0

\* These denote no definite chemical compounds, but simply average formulae.

The heavier mineral oils are said to consist almost entirely of olefines and pseudo-olefines. The average molecular formula obtained for 0.884 oil, although it affords no proof as to the constitution of the components of the oil, tends to bear out that the oil consists of compounds rich in carbon, like the olefine and acetylene series. The difference in percentage composition between these oils and various paraffins and terpenes is not very great, as is shown by the following:—

	Paraffins.		Turpentine Oil.	Olefines.	0.884 Mineral Oil.
	Octane, C <sub>8</sub> H <sub>18</sub>	Decane, C <sub>10</sub> H <sub>22</sub>	C <sub>9</sub> H <sub>18</sub>	C <sub>10</sub> H <sub>18</sub>	C <sub>10</sub> H <sub>16</sub> (found.)
C	84.2	84.5	85.2	88.2	86.68
H	15.8	15.5	14.8	11.8	11.67

Octane, Decane, and Turpentine Oils.

The experiments with octane, decane, and turpentine were undertaken in order to ascertain how far the results differed, in destructively distilling at a moderately high temperature, liquids containing approximately the same percentages of C and H, but widely differing in constitution and in complexity of molecular structure. Octane, prepared from octyl iodide and having a boiling point of 122° C., was decomposed at 600° C. and 800° C. in the 8 in. × 3 in. retort. Decane from iso-amyl iodide, and boiling at 156.5° C., was decomposed in a similar manner. Turpentine oil (portion distilling = 92 per cent. 154°—158° C.) was decomposed in 6 in. × 36 in. retort. The results are embodied in Table II.

Norton and Andrews, on decomposing pentane and hexane, by passing the vapours of these paraffins through a red-hot tube, found that decomposition set in about 600° C. The products obtained at that temperature were ethylene, propylene, butylene, and paraffins. Benzene was formed from hexane at higher temperatures. From the results on Table II., it will be seen that, while octane gave at 550° C. 23 per cent. of unsaturated hydrocarbons, equivalent to 30 per cent. of ethylene, at 800° C. only 12.3, equivalent to 11.7 per cent. ethylene, were obtained. Similarly, decane at 550° C. gave 27.4 unsaturated hydrocarbons, equivalent to 32.1 per cent. ethylene, and at 800° C. 13.4, equivalent to 14.2 per cent. ethylene. These results bear out that at low temperatures octane and decane are decomposed into ethylene and higher olefines, methane, and hydrogen, while at high temperatures no higher olefines are formed, the gaseous products being simply ethylene, methane, and hydrogen.

It has been shown by Professor Tilden (Journ. Chem. Soc. 1884, page 410) that the products obtained from

ordinary turpentine oil at a low red heat, consist chiefly of *pinene*, *heptene*, *metaxylene*, *cymene*, and *terpene*, with small quantities of benzene and toluene. The results embodied in the foregoing table show that at 800° C., turpentine oil is capable of yielding a large volume of gas, 63.3 cubic feet, with an illuminating value of 39.1 candles, having been obtained. The residuals amounted to 16.6 per cent., and when fractionally distilled gave a total distillate up to 100° C. of 12.2 per cent.

The percentages which came over every 10° degrees up to 210° C. are shown by the following diagram:—

PERCENTAGE OF RESIDUE FROM TURPENTINE OIL,  
DISTILLING EVERY 10° FROM 60° TO 210° C.

The portion distilling below 106° C. was nitrified, the amount of benzene found being 3.7 per cent. of total residue. The distillate between 110°-120° C. consisted principally of toluene, while the portion distilling between 130°-170° C. (42.2 per cent.) is due to *cymene* and isomeric *terpene*.

Summarising the results on Table II., it has been found that on submitting members of paraffin, olefine, and terpene series to destructive distillation about ordinary temperature

employed in oil-gas manufacture, they tend invariably to split up into simpler members, with the evolution of gaseous members of the olefine and paraffin series and free hydrogen. The rupture between carbon and hydrogen is greater as the temperature rises. A glance at the percentages of

FORM OF APPARATUS USED IN DETERMINING ULTIMATE  
SPERM VALUE.

unsaturated hydrocarbons found will show what each series is capable of. Lower paraffins give a smaller percentage than terpenes, while terpenes again have a less percentage than higher paraffins. As might naturally be expected, the percentage is highest in liquids where the higher olefines form the greater part. From this circumstance, heavy mineral oils are more suitable for oil-gas making than Russian petroleum, and the latter than American petroleum, the olefines being highest in Scotch oil, next in the Russian, and least in the American.

#### Oil-Gas Enrichment.

In 1884, Professor P. F. Frankland read a paper on "The Illuminating Power of Ethylene when Burnt with Non-Luminous Combustible Gases" (*Chem. Soc. Jour.* 4530). He determined the illuminating value of pure ethylene when burnt alone to be equivalent to 68.5 candles per five cubic feet, but on mixing ethylene with various proportions of hydrogen and methane, he found that the intrinsic

illuminating power of the ethylene (calculated to five cubic feet per hour irrespective of the composition of the mixture) was much greater. When marsh-gas was used as a diluent, the intrinsic value of ethylene did not increase to any extent until the proportion present in the mixture reached 50 per cent., when the value rapidly rose as the proportion of methane was increased until 90 per cent. had been added, when the intrinsic value of ethylene reached 170-180 candles.

This fact is of great value when it is desired to enrich a poor coal-gas by the addition of oil-gas of high illuminating power. The proportion employed in practice where oil-gas is used to enrich coal-gas is about 15-20 per cent., and in order to determine the intrinsic value of oil-gas, experiments were made, using varying proportions of oil and coal-gas. The illuminating values of oil and coal-gas being separately determined, various known proportions were run into the large experimental holder. Prior to determining the candle-power each mixture was allowed to stand 14-18 hours to allow complete diffusion of the mixed gases.

The following results were obtained (for Table III, see next page).

#### Size and Shape of Retorts.

It will perhaps be of interest to glance into the conditions (other than temperature and nature of oil used) affecting the production of gas from oil. It is evident that the following factors enter into the question. (1.) Temperature of retort (affected by rate of flow and diameter of retort). (2.) Rate of flow into retort (the length of retort, and temperature modify the effect of rate of flow). (3.) Length of retort in proportion to its diameter (the time during which the vapours and gases are exposed to heat being of course directly proportional to length of retort). (4.) The ratio of total surface to cubical capacity. (The temperature in the centre of a narrow retort corresponds closely to surface temperature. Given a proportionate length, and the wider the retort is, the further is the divergence of temperature between centre and surface, owing to surface exposed being less in relation to cubical capacity.) (5.) The oil used.

The following experiment is an illustration of how a continuous and uniform rate of flow, by reducing the temperature in the interior of retort, affects the composition yield and candle-power of the gas. The oil was sprayed into the fire-clay retort at a rate of 0.42 gallon per minute. The gaseous products at the end of the first, third, and fifth minutes were examined separately, with the following results:—

	Yield.	Candle Power.	Composition of the Gas.		
			CuHm.	CuHn <sub>2</sub> + 2	H.
	Cub. Ft. per Gall.				
End of first minute.	126	24.7	10.5	47.7	41.8
End of third minute.	93	20.5	15.3	50.6	34.1
End of fifth minute.	79	16.6	28.7	48.1	23.1

The effect of different rates of flow is shown by the following:—

Retort.	Time.	Amount of oil used.	Yield per Gallon.	Candle Power.
36 in. x 6 in.	Mins.	Gallon.	Cub. Ft.	
	60	0.25	26	41.1
"	18	0.25	71	58.7

In order to note the effect of prolonging the action of heat on the vapours and gases produced by running the oil into upper retort, an experiment was tried where the upper and

$P_2$  = candle-power of oil-gas as shown by enrichment.

$P_3$  = candle-power of coal-gas.

$P_4$  = candle-power mixture found.

$P_5$  = theoretical candle-power of mixture.

$y$  = coal-gas taken.

$x$  = oil-gas taken.

$C_1$  = candles per cent. of oil-gas.

$$P_5 = \frac{(x \times P_1) + (y \times P_2)}{x + y}$$

$$P_4 = \frac{y(P_3 - P_2)}{x} + P_3$$

lower ones were connected by means of a pipe passing to back of lower one. In this case the ratio between surface and capacity was little altered from first series of experiments, but the time during which the vapours were exposed to the action of heat was doubled. Two experiments were made, (1) with 0.884 oil, and (2) with a sample of coal-tar (splint), sp. gr. 1.17, the rate of flow in each case being the same. The results obtained were as follows, the results from 0.884 oil at 800° C. (given in Table I.) being inserted for comparison:—

Temperature.	0.884 Mineral Oil.		Coal Tar.	
	800° C.	800° C.	960° C.	960° C.

The following table shows the relationship between (1), length and diameter; (2), surface and capacity of some retorts used experimentally and in practice.

	Lewes's Experiments.			Pintsch.
	Patterson. 3 6" x 19.5"	10" x 4"	4" x 2"	2 (76)" x 10"
Length = $h$	4.4	2.5	27	15.2
Diameter = $2r$	..	..	..	..
Sq. ft. of surface per cub. ft.*	5.6	14.4	24.4	5

	Young.		Own Experiments.	
	9" x 2 5/8"	3" x 8"	6" x 36"	(13" x 17 1/2" x 8 1/2")
Length = $h$	4	2.6	6	(6.7)
Diameter = $2r$	..	..	..	..
Sq. ft. of surface per cub. ft.	2	19	8.6	(6.37)

$$\text{* Ratio: } \frac{\text{Total surface of cylinder}}{\text{Total capacity}} = \frac{2\pi rh + 2\pi r^2}{\pi r^2 h} = \frac{2(h+r)}{r^2 h}$$

The results given by Professor Vivian B. Lewes (in his paper on Russian petroleum previously referred to) clearly show the effects of varying the forms of retorts.

It is evident that increasing the length of a retort affects the products of decomposition equally as much as increasing the ratio of square surface to cubical capacity, while the latter ratio is of course little altered. In the Patterson and Young retorts the surface ratios are smallest, while in the Pintsch and other double retorts used in practice, the length

ratio is largest, rendering a large rate of flow necessary for the production of rich gas.

In conclusion I have to express my thanks to Mr. Mackay, lately gas manager at Peterhead, for the facilities afforded in undertaking these experiments, and in a similar manner to his successor, Mr. James Kincaid, for affording me every facility and assistance in carrying them out.

## NOTES ON THE OXIDATION OF ANILINE. (I.)

BY PROF. E. J. MILLS, F.R.S., AND  
WALTER MACFARLANE.

ALTHOUGH the oxidation of aniline has been for many years carried out upon the large scale, it has never been submitted to continuous measurement. The investigation proves, in fact, to be beset with serious difficulties, which we can by no means pretend to have entirely overcome; but we have succeeded in eliciting certain results which may perhaps be of interest.

The substance which we in the first place selected as an oxidiser was mercuric nitrate, one of the substances by which magenta was at one time prepared in a technical scale from aniline. Our sample was made by Morson of London; and was found by a mean of several determinations to have the percentage composition—

Mercuric oxide.....	70.02
Nitric anhydride.....	28.68
Water.....	2.13
	100.83

Mercury was estimated by Hempel's process. Nitric anhydride was determined by treatment with excess of hot baryta-water, passing carbonic dioxide into the solution, filtering, and precipitating the filtrate with hydric sulphate: from the weight of the precipitate, the weight of nitric anhydride could be calculated. Water was estimated by heating to 120° with pure litharge in a current of dry air.

The aniline which we employed had been distilled out during the manufacture of aniline by the arsenic process. Of this, 93 per cent. was volatile at 110°—183°; and the first third of this, an additional distillation, constituted the stock which we used for our experiments.

We had occasion to observe that either pure aniline or "aniline for red," when heated with arsenic pentoxide or mercuric chloride, always gave rise to a little ammonia. Also, on distilling pure aniline with ammoniac nitrate, we readily found that aniline can expel ammonia from its salts.

The measurement of the amount of any one colour formed during the action of mercuric nitrate on aniline is practically out of the question, the reaction being complicated by the variety of coloured products. Fortunately, however, we noticed that nitrogen was always evolved. We therefore arranged the following apparatus for investigating the reaction by collecting this gas under varied conditions as to mass of nitrate.

The apparatus consisted, as shown in the figure, of a cohobation-flask having a long neck, ground into a wider S-tube, itself terminating in a quill delivery; the gas was collected over a pneumatic trough in a graduated cylinder, partially occupied at the outset by air.

In each experiment, 20 cc. (= 20.601 grms.) of aniline were used, the amount of nitrate being varied. The two substances were allowed to remain in contact for 40 minutes, and the necessary readings of volume of air, barometer, and thermometer were made. The aniline was then heated to cohobation (but not so as to pass into the bend) for 210 minutes; and, after remaining over night, the readings were repeated. The results were as follow:—

TABLE I.

No.	Nitrate.	Normal Nitrogen.	No.	Nitrate.	Normal Nitrogen.
	Grms.	Cc.		Grms.	Cc.
1	0.5533	55.8	9	3.0176	111.6
2	0.8101	61.3	10	3.4532	116.4
3	1.0179	83.3	11	3.9183	130.3
4	1.4883	104.6	12	4.0077	133.4
5	2.1132	134.9	13	4.0733	131.0
6	2.4988	138.9	14	4.9929	152.4
7	2.9767	154.3	15	5.7243	137.6
8	2.9067	150.9	16	6.7436	117.8

During the cohobations the colour of the aniline changed to orange, deep orange, and intense mauve-purple. Abundance of mercury was liberated. The product of the reaction was always freely fluid, with more or less discrete solid in suspension. It was evident that there was always an excess of aniline.

The table shows that the interaction, somewhat energetic at first—becomes slower in proportion as the nitrate increases. Experiments 15 and 16 seem to indicate that, when the nitrate exceeds a certain amount, it acts as a retarding agent to its own normal effect. There is clearly a useful limit to the amount of oxidiser that can be used, even with "excess" of aniline. This also is noticed in the ordinary method of manufacturing magenta. In the annexed drawing we have plotted out our experiments and drawn through them the curve.

$$y = \frac{157.8}{1 + 7.5x}$$

(y being nitrogen and x nitrate).

The curve is calculated from the range 3—14 inclusive, the first and last two experiments evidently being not fairly within what we may term the "normal" interaction. The probable error of a single experiment is 4.3 cc.; and reflects well the known difficulty of obtaining regular results as between a solid and a liquid.

According to the equation, no amount of nitrate would in a "normal" experiment, have produced more than 229.3 cc. of gas. The useful limit seems to be when  $\text{Hg}_2\text{N}_2\text{O}_6$  gives rise to an evolution of  $1\frac{1}{2}$  N, which according to the same equation, would correspond to 3.3099 grms. nitrate and 149.2 cc. of gas.

As regards the actual chemical change, we may suppose that  $\text{Hg}_2\text{N}_2\text{O}_6 = \text{Hg} + \text{O}_2 + \text{N}_2\text{O}_4$ . One of the products of

the action of nascent oxygen on the aniline would be water; and one of the products of the action of nitric peroxide and aniline would be a diazo compound. Thus, nitrogen and phenol would be eventual products.

The failure of this process technically was doubtless due in the main to the expense of the reagent. We can now see, however, that the loss of nitrogen and the large excess of aniline required to be present throughout, to say nothing of collateral nitrations and other reactions, must in any event have led to its abandonment.

## NOTES ON THE OXIDATION OF ANILINE. (II.)

BY PROFESSOR MILLS AND GEORGE WATSON, JUN.

A sample of purified aniline from the stock referred to in the preceding note, was cohobated for six hours with mercuric oxide in order to destroy residual toluidine (if any); it was then distilled in a current of steam and dried over caustic potash.

Pure mercuric oxide was prepared by dissolving very pure mercury in aqueous hydric nitrate, and precipitating with caustic soda freshly made from sodium; the washing was for the most part performed in a silver basin. Of two preparations, that used in our first series of experiments was found to contain 0.1 per cent. of impurity, consisting of lime, silica, and alumina; the one used in our second series contained 0.07 per cent. of impurity, chiefly consisting of argentic oxide.

In the course of some qualitative experiments, we found that when mercuric oxide is treated with aniline, neither nitrogen nor ammonia is formed. The principal product was a brown body, apparently of an induline character. Associated with this, when small quantities of oxide were used, were tangible amounts of a red product, which did not seem to be formed when the mass of the oxide was large.

We measured the course of oxidation in the following manner:—Into a flask of about 50 cc. capacity, 10 cc. of aniline were always introduced, and a known but varied amount of oxide. A cohobating tube was attached to the flask, which was then heated for  $3\frac{1}{2}$  hours continuously; the time being reckoned from the commencement of ebullition. The contents of the flask were then digested with alcohol in the cold, and further diluted to a convenient depth of tint. The relative amounts of brown colouring matter were ascertained by colorimetric comparison with one such solution taken as an arbitrary or intrinsic standard (100). These comparisons were made by means of an instrument essentially identical with the "detached colorimeter" designed by one of us (Phil. Mag. June 1879). We found no difficulty in attending to the brown colour solely when making these estimations.

TABLE I.

No.	Oxide.	Colour.	No.	Oxide.	Colour.
	Grms.			Grms.	
1	6.2923	126.9	7	2.5059	58.7
2	5.9709	100.0	8	2.0219	38.8
3	5.1700	102.0	9	1.5490	36.6
4	4.1145	67.6	10	1.1823	24.0
5	3.5410	60.9	11	0.8520	16.9
6	2.9933	55.3			

The results in this table, if graphically represented, lie approximately on a straight line—

$$\text{Oxide} \times 19.55 = \text{colouring matter.}$$

The equation has a probable error of 5.9. We are disposed to regard this set of experiments as somewhat abnormal on account of the presence of water or (which

would come to the same thing) a more easily oxidable matter than aniline. We had, in fact, noticed that the cohobation was unduly concussive.

In the following set of experiments we used another sample of aniline, and ebullition went on quietly.

TABLE II.

No.	Oxide.	Colour.	No.	Oxide.	Colour.
	Grms.			Grms.	
1	5.1700	100.0	5	2.4359	18.8
2	4.8909	67.4	6	1.7495	17.1
3	3.8554	43.8	7	1.3233	12.4
4	2.8188	24.3	8	0.9179	19.7

The results correspond to a hyperbola, whose equation is—

$$y = \frac{6.73x}{1 - .12x}$$

( $y$  = colour,  $x$  = oxide). We subjoin a drawing of this curve, and have plotted round it the experimental quantities. The probable error of a single determination is 5.2.

The equation has a critical value when  $x = 8.3$ . The aniline and oxide are then very nearly in the proportion,  $3C_6H_5N:11HgO$ , and any excess of oxide above this would lead theoretically to a negative result.

In the experiments with the nitrate, it will be remembered that the useful limit appeared to be  $3HgN_2O_6:4N$ . The mathematical relations of the curves show that one of these reactions is distinctly inverse to the other.

## DISCUSSION.

The CHAIRMAN said that arsenic oxide should still be used in making magenta on the large scale, was interesting because it was undoubtedly the first of the methods discovered by Dr. Medlock. It seemed remarkable that oxide of mercury should not evolve nitrogen from aniline, and he asked if other oxidisers behaved similarly? Could Professor Mills give any details regarding the brown substance which he had observed?

Professor MILLS had not separated the brown substance. It was so mixed with other colouring matters as to make its separation a very difficult operation. The research was rather intended as an instance of the mode of measuring, on a small scale, a technical operation. Stirring was effected by means of cohobation, while in the technical operation a screw-stirrer is employed in a horizontal cylinder. So far as he had been able to ascertain, nitrogen had never been observed in this manufacture.

Discussion on Mr. Tocher's paper was postponed until May 1st.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*Improved Method of Setting Up Vessels for Boiling.*  
G. A. Mangoldt. Chem. Zeit. 17, 1899.

WHEN vessels are employed in chemical manufactures heated by direct firing, a frequently occurring inconvenience is that the substances heated are apt to "burn" on the bottom, thereby leading to considerable loss and damage to the rest of the product. To avoid this, the vessel may be conveniently heated by means of one or more circular flues round the sides, through which the flame plays before reaching the bottom. In this way the temperature of the gases is sensibly reduced before they come in contact with the lowest part of the boiler, where dregs and solid impurities, &c., naturally tend to settle; the chance of burning on the sides of vertical and conical boilers is much less than on the bottom. Cylindrical vertical distilling apparatus thus heated are found to form markedly lessened amounts of products of decomposition by overheating; whilst conical soap kettles heated by direct firing, produce a soap less browned and otherwise deteriorated in quality by the burning of insoluble limesoaps, &c., on the bottom. In order to collect such precipitated impurities, the base of the kettle may conveniently be provided with a "hat," or small well at the base, protected from direct contact with the flame. The solid dregs, &c., settle into this. The same arrangement answers well when saline matters "salt out" in consequence of concentration by evaporation.

—C. R. A. W.

*Use of Asbestos for the Filtration of Sugar, Juices, and Syrups.* P. A. Maignen. Bull. de l'Assoc. des Chim. 10, 881.

See under XVI., page 264.

## PATENTS.

*Process for the Distillation of Substances having a High Boiling Point.* Benno Jaffé and Darmstaedter, Charlottenburg, Berlin. Eng. Pat. 1468, January 23, 1893.

THE use of superheated steam for distilling substances not readily volatilised is general, partly because of the assumption that the steam vaporises the particles of the substances that come in contact with it, envelopes the same, and carries them along with it, so as to effect distillation at a temperature below the boiling-point of the substance treated; and partly because it is supposed that if air were employed instead of steam, oxidation or decomposition would be more readily brought about. This, however, is incorrect as regards glycerol; by passing air through glycerol, distillation can begin at 120° C., and is active at 170–180°; the distillate obtained is purer, as no decomposition is brought about at the lower temperature used; the yield is quite as large as that obtained by means of steam. The current of air is propelled by any suitable air-forcing apparatus, the glycerol being heated from the outside. The distillate is free from aqueous particles, and is collected in suitable refrigeration recipients, one or more of the last of which contains some water, so as to remove the last traces of glycerol from the escaping air which forms the vehicle. Aniline and other substances can similarly be readily distilled in a current of any permanent gas that has no detrimental effect upon the substance treated.—C. R. A. W.

*Improvements in and relating to Filtering Apparatus.*  
H. J. E. Jensen, Hamburg, Germany. Eng. Pat. 1780, January 26, 1893.

THE patented improvement refers to filters in which the filtering material, such as asbestos and other fibrous material, is in the first instance mixed with the liquid and deposited upon perforated screens by the aspirating action of the liquid as it is drawn through the said screens. The improvement consists in causing the liquid to approach and pass through the screens at an equal speed over all the exposed surfaces, with a view to obtaining an equal thickness of filtering material throughout, and to preventing its disturbance or washing away afterwards.

For this purpose the inventor proposes to apportion the areas of the holes through the tubes which carry away the filtered liquid, in such a way as to induce equal currents through all parts of the filtering surfaces, one method of arranging them being shown in the accompanying illustrations.

Fig. 1.

*a* is an open cistern into which the liquid to be filtered is run from the shoot *a*, the partition *g* causing it to descend and to reach the filtering units *e* from below. The units consist of frames covered with wire netting, hung from the pipes *b*, with which they communicate through the openings *b*, *c*.

Within the pipe *b* is secured centrally a second pipe *i*, closed at one end and communicating at the other with the outlet opening *h*.

Fig. 2.

Fig. 3.

The inner pipe is perforated with openings diminishing in area towards the outlet end, which is claimed by the inventor to produce the desired equality in the current through the filtering surfaces.—B.

*Improvements in and connected with Gas Producers.* J. J. and T. F. Meldrum, both of Manchester. Eng. Pat. 4076, February 24, 1893.

See under II., page 242.

*Apparatus for Driving Off Heavy Vapours of Solvents.* The Parent Syndicate Oil Extractor Co., Lim., and H. A. A. Dombrain, Bradford, Yorkshire. Eng. Pat. 3040, March 8, 1893.

THE material, containing the solvent, is fed into the lower end of an inclined trough and distributed along it by a pair of worm conveyors. The trough is surrounded by a sheet-metal casing communicating by means of pipes with a water-cooled conduit below, and furthermore is heated by a steam-jacket depending from its under side, whereby the solvent is evaporated and the heavy vapour, escaping into the water-cooled conduit, is condensed.—E. G. C.

*Improvements in the Manufacture or Restoration of Filtering Media.* J. Wetter, London. From M. Weinrich, St. Louis, U.S.A. Eng. Pat. 5375, March 13, 1893.

TO regenerate spent bone-charcoal, whereby it may be used over again for filtering purposes, the bone-charcoal or bone-char is first washed with pure hot water, and, if necessary, treated with such purifying agents as muriatic acid, soda, or ammonia. The wash-water is afterwards drawn off, and a hot solution of crude bone gelatin or dissolved glue is run on to the bone-char, in the proportion of 160 to 240 lb. of solution to 1,000 lb. of bone-char. Steam is now applied to bring the temperature of the mass up to boiling point, and it is kept boiling until the water in the mass is so far reduced in amount, that the gelatin sticks to the particles of bone-char. The mass is now removed, dried, and then charred in suitable kilns, thereby covering the old ineffective surface of the particles with a

new coating. The burned and cooled bone-char is now washed with pure hot water, and is then ready for use. A mixture of gelatin and fresh blood, or fresh blood alone, may be used in place of the gelatin or glue.—E. G. C.

*Improvements in Centrifugal Machines for Separating Liquids.* F. Ludloff, Berlin. Eng. Pat. 5493, March 14, 1893.

THE inventor states that in ordinary centrifugal machines used for separating cream from milk, it is necessary that the speed should be kept even. If slower than the supply warrants, the full quantity of cream is not extracted and the contents are likely to run over. If worked faster than necessary a loss of power ensues.

The patentee proposes to remedy this defect by introducing an automatic arrangement by which, for a reduced speed, a part of the milk under treatment is thrown into a vessel from which it is returned to the original reservoir for a second treatment. The illustration indicates one of

the arrangements, in which *A* is the separating drum, here shown of somewhat spherical shape. The milk reaches it from the spout *E* through the hole *8* in the upper part of the cylindrical neck attached to the drum *A*, inside of which the liquid, on rotation, takes the parabolic form, having the skim milk near the larger diameter of the drum and the cream more towards the centre. The skim milk escapes through the tubes *E'* into the casing *F*, leaving the latter by the spout *f*. The cream-collecting tube *e'* discharges into the lower chamber *G* in a similar manner. If the speed of the drum decreases, the issue through holes *4* diminishes, which causes the supply to rise in the upper cylindrical chamber and finally to overflow into the splash-pan *12*, issuing at *14*, and thus indicating a necessity for increased speed. At too high a speed no such stream of milk is seen at the outlet *14*, and the speed may be diminished until just giving a proper balance. The various holes indicated are originally adjusted for the proper speed desired.—B.

*Improvements in Filtering Sewage.* B. Rushford and J. Edwards, Aldershot. Eng. Pat. 5689, March 16, 1893.

See under XVIII. B., page 271.

*Improvements in Apparatus for Cooling and Evaporating Liquids, such as are used in Breweries and Distilleries, and for such like Purposes.* H. J. Worsam, London. Eng. Pat. 6316, March 24, 1893.

See under XVII., page 269.

*Improvements in Self-acting Apparatus for Raising or Forcing Liquid by Steam, Compressed Air, or other Elastic Fluid under Pressure.* P. Kestner, Lille, France. Eng. Pat. 6165, March 27, 1893.

This invention refers to improvements in the details of an automatic valve arrangement under the previous patent, No. 15,648, 1892 (this Journal, 1892, 394), whereby it is sought, by means of a body suitably arranged in the liquid, that when the receptacle is filled with liquid this body will cause or allow the escape valve to close and the steam valve to open, but when the liquid has been discharged more or less completely from the receptacle, the weight of the said body will effect the opening of the discharge valve and close the steam valve, without requiring first to effect a reduction of pressure in the receptacle.—B.

*Improvements in Vessels for Containing Liquefied Sulphur Dioxide for Use as a Disinfectant and Vermin Destroyer, and for other Medical and Sanitary Purposes.* E. Soy, London. Eng. Pat. 12,276, June 23, 1893.

See under XVIII. C., page 271.

*Improvements in the Method and Apparatus for Producing Gas.* A. Kitson, German Town, Penn., U.S.A. Eng. Pat. 19,521, October 17, 1893.

See under II., page 243.

*An Improved System and Apparatus for Removing Impurities from and Refining China Clay.* W. W. R. Nicholls, W. Nicholls, and F. H. Nicholls, St. Austell. Eng. Pat. 19,699, October 19, 1893.

See under VIII., page 251.

*An Improved Method or Process and Apparatus for Deodorising Oils and Fats.* H. J. Bull, Bergen, Norway. Eng. Pat. 20,413, October 28, 1893.

See under XII., page 261.

*Improvements in Apparatus and Furnaces for Concentrating Sulphuric Acid and other Liquids.* J. Bradbury, Manchester. Eng. Pat. 23,327, November 23, 1893.

See under VI., page 251.

*Improvements in and connected with the Process of and Machinery for the Drying or Heating of Gypsum, Clay, Sand, Grain, Slaughter-house Refuse, and other Materials.* R. Haddan, London. From F. D. Cummer, Cleveland, Ohio, U.S.A. Eng. Pat. 23,045, November 30, 1893.

The apparatus consists of an inclined rotating cylinder, supported at each end on "spiders," one "spider" being operatively connected with the cylinder for driving it by means of suitable mechanism. The material to be heated or dried is fed in at the upper end of the cylinder, and is agitated by means of longitudinal stirrers, fixed to the sides of the cylinder; the material, after passing through the cylinder, falls into a screw conveyor for delivery at any required point. Around the cylinder is built the combustion chamber of a furnace, thereby permitting the hot air and gases to circulate round the cylinder, and also to enter at the lower end and pass through the cylinder to the upper

end, from which they are conveyed away to the flue. An exhaust fan is placed within the flue to cause a current of air through the apparatus, to promote the heating and drying action, and also to more effectively control it than would be the case with a natural draught. Pockets are provided to receive material which may escape from the cylinder, between the "spiders" and the cylinder shell, and this material is afterwards discharged through a suitable drain-pipe.—E. G. C.

*Improvements in or relating to Machinery or Apparatus for Treating, Deodorising, Drying, and Utilising Excreta, Nightsoil, Town's Refuse, and the like.* S. Smithson. Eng. Pat. 23,082, December 1, 1893.

See under XVIII. B., page 271.

*Improvements in the Concentration or Vaporisation of Sulphuric and Acetic Acids, and in Apparatus therefor.* A. J. Boulton, London. From S. C. Penchen and P. Clarke, Toronto, Canada. Eng. Pat. 24,739, December 23, 1893.

See under VII., page 251.

*Improvements in the Manufacture of Sugar.* H. H. Lake. From P. H. Vander Weyde and O. Lugo, New York, U.S.A. Eng. Pat. 136, January 2, 1894.

See under XVI., page 265.

## II.—FUEL, GAS, AND LIGHT.

*General Characters of Boghead Cannel.* C. E. Bertrand and B. Renault. Comptes rend. 1893, 117, 593—596.

THE following are the conclusions drawn from a study of boghead from Autun, kerosene shale from Australia, and Torbane Hill mineral:—

A very simple class of coal exists, which is formed by the accumulation of the fronds of a single species of algae in an ulmic deposit. These vegeto-ulmic deposits indicate tranquil periods during which the algae have multiplied so as to cover the surface of the water, whilst an abundant terrestrial vegetation has scattered clouds of pollen or spores. These vegetable accumulations have been produced on the spot where the algae have lived. The ulmic acid is precipitated under the influence of calcareous water, the algae sink to the bottom and carry with them the soaked pollen or spores, whilst any small floating debris is simultaneously carried down with the ulmic substances. No change, no decomposition has taken place in these vegeto-ulmic deposits. In the case of the three boghead cannel, these deposits have become penetrated by brown infiltrations probably of a bituminous nature: the bitumen possibly owes its origin to the decomposition of a mass of vegetable matter not far removed.

The boghead cannel may frequently be associated with ordinary coal, which they sometimes precede, sometimes succeed: occasionally they occur as intercalated beds in the coal measures, and not infrequently the coal occurs in the boghead cannel. The cleavage of the coal does not extend to the masses of boghead cannel.

The three boghead cannel owe their special characters to the algae composing them, namely, the Autun boghead to *Pila bibraetensis*, kerosene shale to *Reinschia australis*, and Torbane Hill mineral to another *Pila*. If all other conditions are present but the algae are wanting, the coal-bed will not possess the character of a boghead cannel.

Amongst the yellow bodies present in coal are the substances contained in the pollen grains and spores, also those produced by the walls of the fronds of the *Reinschia* and *Pilas*. Those formed by the gelatinised fronds are of a different kind from those produced by the sound fronds.

Then, again, there are yellow particles of animal origin, produced from cartilage, from coprolites, and even from the soft parts of animals embedded in the ulmic deposits.

Diatomaceæ were not found in the three boghead canals.  
—A. K. M.

*Persian Coal.* A. F. Stahl. Teheran. Chem. Zeit. **17**, 1596.

A CONSIDERABLE amount of coal is found in Persia, but for the most part of somewhat poor quality. Owing to the want of proper facilities for transport, but little is actually mined; thus, only 6,000 to 7,000 kharvar (1 kharvar = 280 kilos.), or some 1,500 tons, are yearly brought to Teheran, and sold at a price averaging about 40 kran (1 kran = about 6d.) per kharvar, or something like 4l. per ton. Naturally, industries requiring fuel are not greatly developed under such conditions. Various samples of Persian coal yielded the following figures on proximate analysis:—

No.	Volatile Matter lost on Destructive Distillation.	Coke.	Ash.
	Per Cent.	Per Cent.	
1	12	88	20 per cent.
2	20	80	14 per cent.; also 16 per cent. of stones.
3	19	81	50 per cent. ash and stones.
4	31	69	9 per cent.
5	28	72	27 "
6	27	73	10 per cent.; also 2 per cent. of stones.

As a rule such coal is very brittle and disintegrates spontaneously on exposure to air. In some cases a considerable admixture of pyrites is present, whilst the amount of stony matter is often excessive, owing to defective hand-picking.—C. R. A. W.

*Estimation of Sulphur in Recovered Gas-purifying Material.* F. Meyer. Chem. Zeit. **17**, 1319.

See under XXIII., page 283.

## PATENTS.

*An Improvement in Incandescent Gas Burners.* O. Imray, London. From J. Moeller, Paris. Eng. Pat. 124, January 3, 1893.

This invention relates to the kind of burner described in Eng. Pat. 15,286, 1885, in which a network hood of metallic oxide is heated to incandescence by a Bunsen flame. The improvement consists of making the hood of oxide of thorium, to which not more than 2 per cent. of the oxide of other rare metals, such as "uranium, cerium, terbium, neodymium, praeodymium, samarium, yttrium, or lanthanum," has been added.—R. B. P.

*Improvements in or relating to the Manufacture or Production of Block Fuel, Gas and other useful Products from Refuse Material.* J. C. W. Stanley, Middlesex. Eng. Pat. 2247, February 1, 1893.

THE process described in this specification relates to a method of treating what is known as "dust-bin" refuse,

from which waste paper, &c. has been removed in the manner described in Eng. Pat. 1510, 1889, so as to separate the various materials it contains, in order that they may be subsequently utilised.

The process consists of a series of siftings, washings, and filterings. The final products obtained are stated to be, "unburnt coal, burnt coal (floats and cinder), mixed coal and cinder, clean-washed sand, filter-pressed cakes, mud containing potash and nitrogen.—R. B. P.

*An Improved Method of Preparing Peat for Heating, Gas Generating, and other Purposes.* T. A. Dillon, Dublin. Eng. Pat. 3554, February 17, 1893.

This invention consists in mixing peat with mineral, or vegetable oils, fats, or resinous substances, by aid of an alkali, and thus making even moist peat into a satisfactory fuel.—R. B. P.

*An Improvement in Apparatus for the Manufacture of Water-Gas.* J. R. Paisley, Colnbrook. Eng. Pat. 3815, February 21, 1893.

This invention relates to an improvement in the cooler of the apparatus described in Eng. Pat. 15,797, 1889, and has for its object the prevention of the cooling pipes becoming choked by the dust which enters with the gas. This is effected by prolonging the lower ends of the cooling pipes into a trough, which forms a water seal. Passages for the gas from one pipe to the next are provided just above the water seal. By these means, whilst the gas flows through the cooler in the usual way, the dust entering with it, falls through the prolongations of the cooling pipes into the trough forming the water seal, and choking of the pipes is prevented.—R. B. P.

*Improvements in or connected with Gas Producers.* J. J. and T. F. Meldrum, both of Manchester. Eng. Pat. 4076, February 24, 1893.

This invention relates to producers closed at their lower end by a water seal, and into which air is introduced by means of a steam blower through a tuyère situated near the lower part of the producer. Figs. 1 and 2 show a sectional elevation and plan respectively, of the apparatus.

Fig. 7

*b* is the tuyère, resting on a raised wall *c* (Fig. 2), and *c* the blower. *h h*, are pits forming the water seal, from which ashes can be withdrawn. —R. B. P.

*Improvements in the Manufacture of Illuminating Gas, Artificial Fuel Blocks, and Coke for Metallurgical Purposes.* G. de Velna, Paris. Eng. Pat. 6951, March 21, 1893.

This process consists in adding hydrocarbons formed into an emulsion to any kind of coal, whereby a better quality and yield of gas is obtained. The emulsion is prepared by suitably mixing together and heating the following substance:

	Parts.
emulsion of, or any fatty acid .....	2 to 10
residual ley .....	0.1 to 1
Tar of petroleum or schist .....	89 to 98

—R. B. P.

*Improvements in and connected with Means or Apparatus for Drying, more especially intended for Peat.* J. D. Brunton, Westminster. Eng. Pat. 6770, March 30, 1893.

In this process the peat is first moulded into bricks by a suitable machine, which delivers them on to a table consisting of a series of rotating parallel rollers, carried on a trolley. The mechanism is such that the bricks are regularly delivered on to suitably-heated drying floors from the moulding machine. It not only causes the passing of the peat bricks across the drying floor, but, as the bricks are turned over each time they pass from one strip to the next, it assists in the proper drying of them. The last strip delivers the dried bricks on to a suitable conveyor. —R. B. P.

*Improvements in the Method of and Apparatus for Producing Gas.* A. Kitson, German Town, Penn., U.S.A. Eng. Pat. 19,521, October 17, 1893.

The distinguishing feature of this apparatus is an inclined hearth which can be simultaneously rotated and raised, or lowered, whereby the fuel is kept in a uniform state of compactness, its surface clean, and the formation of clinker prevented. *E* is the inclined hearth, which is supported by the hollow shaft *G*. *G* is rotated by gearing and caused to rise or fall by the screw and nut at its lower end. *J* is a water-circulating coil connected to the reservoir *J*, as is also the steam-superheating coil *K*. *L* is an oil-vaporising coil connected at *L'* with the oil-supply pipe, and at *L''* with the

superheating coil, steam from which forces the oil through *L*, in which it is subjected to the heat of the furnace, and then into the furnace chamber through the openings *l' l''*. Air is supplied to the fuel in *A* through *G*, at the upper

end of which is a grating *c*. Over *c* are placed pieces of fire-brick or other refractory material. The air is heated before entering, by causing it to pass along a jacket surrounding the gas outlet from *A*. *S* is a hollow rotating plug for feeding in the fuel without allowing any gas to escape. —R. B. P.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Petroleum in Persia.* A. F. Stahl. Chem. Zeit. 17, 1102.

PETROLEUM is known in many places in Persia, but has not as yet been satisfactorily examined. An English company possessing the mining rights for most minerals in Persia, has undertaken during the last three years, boring experiments in Daliki, about 90 km. north-east of the harbour Bushire and on Kishm Island in the Persian Gulf, but without success. Traces of oil may be found all along the west and south-east coast, and in the interior of Persia, pointing to the probability of prolific oil beds. The oil wells east of Kutweis and Ahwaz, on the River Karoon, have yielded for many years a light-coloured oil, which the inhabitants obtain in a very primitive manner.

In November 1891, the author discovered a petroleum well south-east of Semnoon, on the road between Teheran and Meshed, in the Great Salt Desert, which he considers would be well worth boring trials.

After giving a geological sketch of the district, he goes on to show that on sinking 6 metres in the bluish clay, he obtained an output of 40–50 gallons oil per day, mixed with concentrated salt water. This oil has a specific gravity of 0.911. A distillate was obtained at 250° C. of sp. gr. 0.853. Later, another distillate at 200° C. showed a specific gravity of 0.815. The use of 15 per cent. of sulphuric acid failed to remove the yellow colour of the oil, which the author attributes to the high percentage of paraffins present.

The oil beds seem to be near the surface, and the geological structure points to a larger yield. There is no lack of inducement for boring experiments, and, as the use of oil in Persia for lighting purposes is increasing, there is no reason to doubt that an important industry may be developed.

—H. M.

*The Estimation of Paraffins.* R. Holand. Chem. Zeit. **17**, 1893, 1473, 1483.

See under XXII., page 286.

*Cresol as an Antiseptic.* Lauroix Hunkiahyendiau. J. Pharm. Chim. **23**, 34.

See under XX., page 273.

#### IV.—COLOURING MATTERS AND DYES.

*The Auramines.* A. Stock. J. prakt. Chem. **47**, 401–413.

The author has prepared and investigated the following auramines: Acetylphenylauramine, methylphenylauramine, diphenylauramine, and pentamethylene-auramine, and, on account of the existence of the di-substituted derivatives, he considers that they are derived from triphenylmethane compounds in such a way that a benzene ring is eliminated and replaced by an amido-group.

The colour of these compounds depends on the basicity of the amido-group. If this be strongly basic the colour is yellow, and as the basicity gradually diminishes the colour passes through yellowish-red into red. Alkalis as well as acids decompose the di-substituted auramines with the production of the corresponding ketone and amine. By the action of dry ammonia the amido-group is replaced by  $\text{NH}_2$ , the corresponding secondary amine being split off. Aqueous ammonia plays the part both of an alkali and of dry ammonia. As the basicity of the amido-group increases the latter reaction predominates.—J. S.

*The Carboxyl Derivatives of Dimethylaniline.* C. Lauth. Comptes rend. 1893, **117**, 581–583.

The author has examined the three isomeric dimethylanilidobenzoic acids  $(\text{CH}_3)_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{COOH}$ , with the view of determining the influence of the carboxyl group and of its position in the molecule. It is found that by the action of oxidising agents such as cuprous chloride or chloranil, the *ortho*-compound yields a reddish-violet tetramethylrosanilinecarboxylic acid which differs from the ordinary colouring matters of the triphenylmethane

series in being soluble in alkalis, from which solutions it is precipitated by acids. *o*-Dimethylanilidobenzoic acid gives a condensation product with tetramethyldiamidodiphenylcarbinol, which, when oxidised by means of lead oxide, gives a violet blue hexamethylrosaniline-carboxylic acid; it also yields a blue colouring matter—

with benzaldehyde and its metanil derivatives. *Para*-dimethylanilidobenzoic acid also yields condensation colouring matters, but the carboxyl group becomes eliminated. *Meta*-dimethylanilidobenzoic acid gives no colouring matter on oxidation, none with the aldehydes, and only a trace with tetramethyldiamidodiphenylcarbinol.—A. K. M.

*The Colouring Principles of Rubia Sikkimensis.* A. G. Perkin and J. J. Hummel. Proc. Chem. Soc. 1893 [128], 200.

The authors have separated both purpurin and munjistin or purpuroxanthinecarboxylic acid from this root; they point out that the results show that it is nearly identical as regards colouring principles with the closely allied *Rubia munjistin*.

*The Colouring and other Principles contained in Chara Root.* A. G. Perkin and J. J. Hummel. Proc. Chem. Soc. 1893 [133], 201.

CHAY root is the root of *Oldenlandia umbellata*, and is used as a dye-stuff in India; a large number of distinct products were isolated by extracting it either with an aqueous solution of sulphurous acid, or with lime-water, alcohol, and other solvents, viz., two substances of the formula  $\text{C}_{16}\text{H}_{12}\text{O}_5$ , both of which are shown to be autragalloldimethyl ethers; a monomethyl ether of alizarin crystallising in orange needles melting at 178°–179°; a resinous yellow substance, possibly an isomeric methyl ether of alizarin in an impure form; methoxyanthraquinone; a red substance melting at 141°, which yields alizarin with sulphuric acid; ruberythric acid; rubichloric acid; alizarin; a wax of the formula  $(\text{C}_{30}\text{H}_{15}\text{O})_2$ , melting at 87°–88°; and cane sugar.

#### PATENTS.

*Improvements in the Production of Diamido-naphthalene-sulpho Acid and Amidonaphthol Sulpho Acid, and Colouring Matters from the latter.* S. Pitt, Sutton. From L. Cassella and Co., Frankfort-on-the-Maine, Germany. Eng. Pat. 4613, March 2, 1893.

By suitably nitrating and reducing naphthalene  $\beta$ -sulphonic acid, it is converted into a 1'1'-diamido-naphthalene derivative (Eng. Pat. 6972 of 1891; this Journal, 1892, 345). If the  $\alpha$ -acid be treated in a similar manner the main product formed during the mono-nitration is the 1'1'-nitro-naphthalene sulphonic acid, whilst the 1'4'-acid is only formed in small quantity. As, however, it is only the latter which is of use for conversion into the 1'1'4'-diamido-naphthalene sulphonic acid, another method has been devised for the preparation of the 1'4'-acid:—173 kilos. of  $\alpha$ -nitronaphthalene are converted into mono-sulphonic acid. After sulphonation the melt is cooled to 10° C. and 150 kilos. of nitrosulphuric acid, containing 63 kilos. of  $\text{HNO}_3$ , are run in at 15–20° C. The whole is then allowed to stand for 24 hours, and afterwards poured into 3,000 litres of brine. The greater part of the 1'1'4'-dinitro-naphthalene sulphonic acid separates as a brownish crystalline precipitate, which, after filtering, is washed with brine until free from acid. In order to reduce it, the dinitro acid is dissolved in 2,000 litres of water and heated with iron and a little acetic acid. After the reduction is complete the iron is precipitated with sodium carbonate, and 400 kilos. of sulphuric acid are added

to the filtrate. On cooling, the sulphate of the diamido acid crystallises out in colourless needles. The acid has the following constitution.—

It combines with one or two molecules of a diazo compound and yields characteristic salts with mineral acids. It only combines with one molecule of nitrous acid, forming an azimide. The free acid is nearly insoluble in water, and may be obtained by carefully acidifying a solution of its sodium salt. The sodium salt may be salted out by means of common salt. By heating with mineral acids or caustic alkalis the acid is converted into 1'-amido-naphthol sulphonic acid, the best method being as follows:—10 kilos. of diamidonaphthalene sulphonic acid are heated for 12 hours "in a covered vessel" with 100 kilos. of dilute sulphuric acid containing from 20 to 30 per cent. of  $\text{H}_2\text{SO}_4$ . The amidonaphthol sulphonic acid separates in colourless needles from the cold solution. The acid dissolves sparingly in cold water. When treated with nitrous acid it dissolves with a yellow colour, forming an unstable diazo compound. The colour is changed to violet-red by the addition of sodium carbonate. The salts of the new acid are very soluble and show a violet fluorescence in an aqueous solution. The acid is capable of combining with one or two molecules of a diazo compound. The combinations with tetrazo compounds can take place in an acid or alkaline solution, producing different shades, and the usual variations in the components can be made. The colouring matters produced dye shades which lie towards the blue end of the spectrum, and certain of the combinations yield blue and greenish-black dyes.—T. A. L.

*The Manufacture or Production of Direct-dyeing Colouring Matters.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 4756, March 4, 1893.

By combining the diazo compounds of dehydrothio-*p*-toluidine, dehydrothio-*m*-xylidine, dehydrothio-*z*-cumidine, primuline base or their sulphonic acids with the monoalkylated 1'-1'-dihydroxynaphthalene sulphonic acids, direct-dyeing cotton colouring matters of bluish-red shades are produced (Eng. Pat. 3495 of 1893; this Journal, 1894, 145). On further investigating the behaviour of  $\alpha$ -naphthol sulphonic acids towards the above diazo compounds, it has been found that the colouring matters derived from the 1-3 acid give bluish-red shades fast to acids and alkalis, whereas the colouring matters from the 1-2, 1-3', or 1-2' acids only yield dull shades. The colouring matters produced are also superior to the dyestuff known as "Erica," which is formed by combining diazotised dehydrothio-*m*-xylidine with  $\alpha$ -naphthol-6-disulphonic acid—

The formation of the colouring matter from dehydrothio-*p*-toluidine sulphonic acid is described as follows:—34.2 kilos. of sodium dehydrothio-*p*-toluidine sulphonate are dissolved, together with 6.9 kilos. of sodium nitrite, in about 300 litres of water, and hydrochloric acid is allowed to run in until the liquid is strongly acid. After about 12 hours, the diazo compound thus produced is added to a solution containing 24.6 kilos. of the sodium salt of the 1-3-naphthol sulphonic acid made alkaline with sodium carbonate. After standing 12 hours the mixture is heated to about 96° C., and the dyestuff is salted out and filtered off. It gives bluish-red shades on unmordanted cotton.

—T. A. L.

*The Production or Manufacture of Colouring Matters and Materials therefor.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 4757, March 4, 1893.

The first part of this specification relates to the production of alkylated *p*-phenylene diamine thiosulphonic acids, which subsequently are employed for the preparation of colouring matters. By adding two molecular proportions of sodium thiosulphate dissolved in water to a solution of one molecular proportion of a nitroso compound of a tertiary or secondary amine made acid with two molecular proportions of acetic acid and subsequently heating the resulting mixture to the boil, the yellow colour of the solution disappears, but no sulphur separates, and after a short time the liquid is of a slightly brownish colour, and the thiosulphonic acid derivative thus formed can be employed in the production of dyestuffs. The following quantities are given for the preparation of one of the thiosulphonic acids referred to:—34.2 kilos. of the sodium salt of nitroso-ethyl-benzyl-aniline sulphonic acid and 36 kilos. of a 33 per cent solution of acetic acid are dissolved in 200 litres of water and added to a solution of 50 kilos. of sodium thiosulphate in 200 litres of water. The liquid is heated to boiling until the original yellow colour has become fawn. The solution then contains the thiosulphonic derivative of *p*-amido-ethyl-benzyl-aniline sulphonic acid and may be used directly for the production of dyestuffs. It nitroso-dimethylaniline hydrochloride be employed instead of the nitroso-ethylbenzyl-aniline sulphonic acid, the resulting compound is *p*-amido-dimethylaniline thiosulphonic acid. The amido-methyl-*o*-toluidine thiosulphonic acid obtained from nitroso-methyl-*o*-toluidine forms granular crystals. The production of colouring matters from these thiosulphonic acids is an extension of the method described in Eng. Pat. 825 of 1893 (this Journal, 1894, 31). The solution of the thiosulphonic acid from the 34.2 kilos. of nitroso-ethyl-benzyl-aniline sodium sulphonate described above, is, after boiling, mixed directly with 28 kilos. of  $\beta$ -naphthoquinone *p*-sulphonic acid. The dyestuff commences to form at once, and the reaction is completed by heating the mixture for several hours to 80—100° C., when the colouring matter separates in bronzy crystals, which can be filtered off. The product is identical with that obtained from  $\beta$ -naphthoquinone *p*-sulphonic acid or from 1-2,4-dihydroxynaphthalene sulphonic acid and nitroso-ethyl-benzyl-aniline sulphonic acid in the presence of thiosulphates, as described in Eng. Pat. 825 of 1893. A dyestuff from dimethyl *p*-phenylene diamine thiosulphonic acid is produced by dissolving 25 kilos. of it and 25 kilos. of crystallised sodium acetate in 750 litres of hot water and mixing this with a solution of 28 kilos. of the potassium salt of  $\beta$ -naphthoquinone 3'-sulphonic acid dissolved in 200 litres of water. The whole is then heated for several hours to 70—100° C. until the condensation is complete. The product probably possesses the following formula:—

The colouring matter is very similar to the dyestuff obtained by sulphonating the product from nitroso-dimethylaniline, sodium thiosulphate, and  $\beta$ -naphthoquinone 4-sulphonic acid and gives blue shades on wool mordanted with chromium salts. Other blue dyestuffs are obtained by condensing dimethyl-*p*-phenylene diamine thiosulphonic acid with  $\beta$ -naphthoquinone-disulphonic acid. One of these, the  $\beta$ -naphthoquinone-2'-1'-disulphonic acid, can be obtained by oxidising one molecular proportion of 1-2-amido-naphthol-2'-1'-disulphonic acid with one molecular proportion of bromine in a suitable diluent or solvent and subsequently precipitating the acid as potassium salt by the addition of potassium chloride. By condensing  $\beta$ -naphthoquinone-4'-1'-disulphonic acid or its salts with dialkyl-*p*-phenylene diamine thiosulphonic acid, the same

dyestuffs are formed as those obtained from  $\beta$ -naphthoquinone-1'-sulphonic acid, as in the former case the one sulphonic acid group is split off during condensation. The  $\beta$ -naphthoquinone-1'-disulphonic acid is obtained by reducing an azo dyestuff from  $\alpha$ -naphthol-4'-disulphonic acid and oxidising the 2'-amido-naphthol-4'-disulphonic acid produced with one molecular proportion of bromine and salting the product out with potassium chloride. The potassium salt thus formed yields orange-red crystals sparingly soluble in a solution of potassium chloride.

—T. A. L.

*The Manufacture and Production of Sulpho Acids of the Naphthalene Series and of Colouring Matters Obtainable therefrom.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 4979, March 7, 1893.

Isocyanides of the naphthol sulphonic acids are known as "sultones." Hitherto, only one of the corresponding anhydrides from an amido-naphthalene sulphonic acid has been described by Berntsen (Ber. 23, 3094), who produced it by heating the colouring matter from diazotised xylydine and  $\epsilon$ -naphthol sulphamidosulphonic acid with a dilute solution of sodium carbonate, and subsequently reducing the dyestuff thus formed. The resulting acid has the following constitution:—

Bodies of this type are produced from these naphthylamine sulphonic acids which contain an amido and a sulphonic group in the 1'- or peri position, by heating them with fuming sulphuric acid, and the products obtained are known as "naphthasultame sulphonic acids." Occasionally simultaneous sulphonation takes place. The following perinaphthylamine sulphonic acids can be used:—1'-naphthylamine sulphonic acid, 1'-4'-naphthylamine disulphonic acid (both of Ger. Pat. 40,571), 1'-4'-naphthylamine disulphonic acid, 1'-2'-naphthylamine disulphonic acid (Ger. Pat. 45,776), and 1'-2'-3'-naphthylamine trisulphonic acid. The method employed for producing the anhydride is, stirring the acid sodium salt of the acid into twice its weight of fuming sulphuric acid containing 40 per cent. of anhydride and heating the solution at 80°–90° C., until a test no longer gives a diazo compound or forms a dyestuff with diazobenzene sulphonic acid. The melt, which has become solid, is then diluted with ice water, neutralised with lime, filtered, and the solution evaporated down. The sodium salt when dried at 160° C. has the following composition:—

It is very easily soluble in water, but almost insoluble in absolute alcohol. Its solution in water is yellow and exhibits a strong greenish fluorescence similar to fluoresceine. The yellow colour and fluorescence disappear on adding an acid, even acetic acid, and when salt is added to this solution, white needles of the di-sodium salt crystallise out. These naphthasultame sulphonic acids remain unaltered by boiling with alkali lye, ammonia, or dilute acids, differing in this respect from the sultones, which are hydrolysed by this treatment. By fusing with  $2\frac{1}{2}$  times their weight of potash or soda and one-fifth their weight of water, they are converted into amido-naphthol sulphonic acids, which are known as peri amido-naphthol sulphonic acids. They are to be employed as components in the various methods for the production of azo dyestuffs.—T. A. L.

*Improved Manufacture of Colouring Matters.* C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 5039, March 8, 1893.

The 1'-1'-amidonaphthol disulphonic acid of Eng. Pat. 2984 of 1893 (this Journal, 1891, 32) can combine with various diazo compounds to form azo colouring matters. If tetrazo compounds be employed the usual modifications in the methods of combination may be carried out with the new amidonaphthol disulphonic acid. The shades obtained comprise reds, violets, and blues.—T. A. L.

*Improvement in the Production of Disazo Dyestuffs from Gamma "Amidonaphthol" Sulpho Acid.* S. Pitt, Sutton. From L. Cassella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 5141, March 9, 1893.

This is an extension of Eng. Pat. 16,699 of 1889 (this Journal, 1890, 935), and refers to the substitution of *p*-diamidodiphenylamine for the *p*-diamines there described. The dyestuffs obtained are very similar, being a little bluer in shade. According to this specification a colouring matter which dyes unmordanted cotton a bluish-black is obtained by suspending 30 kilos. of *p* diamidodiphenylamine sulphate in 400 litres of water and 40 kilos. of hydrochloric acid, diazotising this quantity with 14 kilos. of sodium nitrite at 0° C., and pouring the solution of the tetrazo compound, which is of a yellowish colour, into 1,000 litres of water in which 60 kilos. of  $\gamma$ -amidonaphthol sodium sulphonate are dissolved, the whole being kept alkaline by an excess of soda. A dark violet precipitate separates, which after 12 hours changes to a dark blue. After heating to about 80° C. the dyestuff is salted out. Other combinations may be obtained in a similar manner.

—T. A. L.

*Improvements in the Manufacture of Coloured Marking Inks and Marking Ink Pencils.* J. Hickisson, Hackney. Eng. Pat. 5316, March 11, 1893.

For use with a pen, an ink is prepared by dissolving one of the "oil-anilines" in castor oil, adding a small amount of india-rubber solution and a suitable mordant, and thinning down the mixture with turpentine. The colour may be brightened by the addition of a dye if desired. For pencils, one part of gum tragacanth, one part of china clay, one quarter part of borax, and three of oil-aniline are mixed together; the fabric is greased, mordanted (if no mordant is present in the pencil), and written on, and finally a hot iron is passed over the mark. The materials prescribed in Eng. Pat. 15,320 of 1887, are recommended as mordants.

—F. H. L.

*The Production of New Disazo Colouring Matters.* S. Pitt, Sutton. From L. Cassella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 5407, March 13, 1893.

The colouring matters described are obtained by combining tetrazo compounds with the alkylated derivatives of amidonaphthol disulphonic acid II. The preparation of this acid is described in Eng. Pat. 1742 of 1891 (this Journal, 1891, 918). For the production of the ethyl derivative 36 kilos. of the neutral sodium salt of 1'-1'-2'-3'-amidonaphthol disulphonic acid (acid II) are heated in an autoclave with 11 kilos. of ethyl bromide, 60 kilos. of calcium carbonate, and some dilute alcohol of 50 per cent. for 20 hours to 60° C. After filtering, the liquid is made acid with 12 kilos. of hydrochloric acid, and, after separation from a small quantity of unaltered acid, the filtrate is concentrated, and on cooling, the ethylamido-naphthol disulphonic acid II separates in thin colourless needles. The acid is easily soluble in water, less so in strong alcohol. It gives an easily soluble nitroso-amine with nitrous acid. The methyl or benzyl derivatives are obtained in a similar manner. All these compounds combined in an alkaline solution with the tetrazo derivatives of *p*-diamines

such as benzidine, tolidine, diamido ethoxy-diphenyl, diamidodiphenylether, &c., give blue dyestuffs for cotton of a very greenish shade. They differ from the products obtained by treating with halogen alkyls and an alkali those diazo derivatives of the amidonaphthol disulphonic acid II which are obtained in an acid solution and contain a free hydroxyl group. The technical value of the derivatives from the new acid consists in their greenish-blue shades, and the acid may therefore be used with advantage as a second component in the case of mixed diazo compounds. The following example shows the method employed:—The tetrazo compound from 18.4 kilos. of benzidine is cooled to 0° C. and added quickly to a solution of 42 kilos. of sodium carbonate in 400 litres of water. Immediately afterwards a neutral solution of 37 kilos. of 1.1'-2.3-ethyl-amido naphthol disulphonic acid is added, the whole being well stirred. The resulting intermediate compound separates as a blue-black precipitate, and a neutral solution of 24 kilos. of  $\gamma$ -amidonaphthol sulphonic acid is added. The intermediate compound gradually dissolves, and the dyestuff separates as a dark-coloured precipitate. It dyes unmordanted cotton a blue-black. The methyl or benzyl compound may be employed in place of the ethyl derivative without altering the properties or shades of the dyestuffs produced.—T. A. L.

**Production of Colouring Matters.** O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brünig," Höchst-on-the-Maine, Germany. Eng. Pat. 5690, March 16, 1893.

AN extension of Eng. Pat. 19,820 of 1892 (this Journal, 1893, 922), substituting for the dinitrochlorobenzene there mentioned, picryl chloride, dinitrochlorobenzenes, nitrobenzyl chlorides, &c., and reacting with them on tetra-ethyl- or tetra-methyl-*m*-amido phenolphthalein to form dyestuffs. The colouring matters are easily soluble in alcohol and acetic acid, and some of them also in water, and those from tetra-methyl-*m*-amido-phenol separate from their solutions as small crystals. The dyestuffs produce bluer and faster shades than rhodamine on mordanted cotton, whilst the shades on wool are yellower. A solution of 25 kilos. of picryl chloride and 44 kilos. of tetra-ethyl-*m*-amido-phenolphthalein in 75 kilos. of alcohol is boiled for a few hours, when the alcohol is distilled off and the colouring matter, which forms a tough mass, is either dried as such, or after having been dissolved in hot dilute hydrochloric acid, is filtered and the dyestuff precipitated from the filtrate by adding salt.—T. A. L.

**Manufacture of Acid Colouring Matters, being the Sulphonic Acids of Alkyl Derivatives of the Diamido-diphenyl-m-tolyl-carbinol.** O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brünig," Höchst-on-the-Maine, Germany. Eng. Pat. 5691, March 16, 1893.

THESE colouring matters are obtained by sulphonating the alkyl derivatives of diamidodiphenyl-*m*-tolyl-carbinol of the general formula—

The leuco bases are produced by condensing *m*-tolyl aldehyde ( $\text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{COH}$ , b.p. 199–200° C.) with secondary or tertiary aromatic bases. These leuco bases are sulphonated, and the leucosulphonic acids oxidised, or the same products may be obtained by first oxidising the leuco base and then sulphonating the carbinol thus produced. The following example gives the quantities employed:—59.6 kilos. of diethylaniline, 22 kilos. of concentrated sulphuric acid, and 24 kilos. of *m*-tolylaldehyde are heated for three days in a lead-lined vessel to 100° C. with constant agitation. After having been made alkaline, the melt is distilled with steam, and the leuco base remaining behind is boiled with water until no longer alkaline, and then dried at

100° C. In order to sulphonate it, it is dissolved in five times its weight of sulphuric acid monohydrate and the solution thus obtained is heated for some time to 80–90° C. until a sample dissolves completely in ammonia. The melt is then poured into water and converted into the calcium salt. The leuco calcium salt is dissolved in 50 times its weight of water, sulphuric acid (three equivalents) is added, and the solution is oxidised with the necessary quantity of lead peroxide. After filtering off the lead sulphate the blue solution is evaporated to dryness. Instead of first sulphonating and then oxidising, the leuco base may be oxidised, and the carbinol, a green colouring matter, afterwards sulphonated. In place of the diethylaniline employed above, the following secondary and tertiary aromatic bases may be used:—monomethyl or ethylaniline or *o*-toluidine, dimethylaniline or *o*-toluidine, diethyl-*o*-toluidine, methyl- or ethyl-benzylaniline.—T. A. L.

**Manufacture of Thionine Colouring Matters Dying on Mordants.** O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brünig," Höchst-on-the-Maine, Germany. Eng. Pat. 5692, March 16, 1893.

THE process consists in blowing air through an alkaline solution of gallic acid or analogous bodies and the thio-sulphonic acids, mercaptans or disulphides, produced, according to Ger. Pat. 15,879, from the following diamines:—*p*-phenylene diamine, dimethyl-, diethyl- mono-ethyl-*p*-phenylene diamines, or ethyl-*p*-tolylene diamine: 2.5 kilos. of *p*-amido dimethylaniline thio-sulphonic acid and 1.7 kilos. of gallic acid are dissolved in 40 litres of water, heated to 60–80° C., and mixed with 4 kilos. of sodium hydrate as soda-lye. Air is then blown through the mixture until the formation of the colouring matter is complete, when it is precipitated by adding salt. The sodium salt is decomposed by acetic acid, and the acid colouring matter, which dissolves with difficulty, is made into a paste. It forms small bronze-coloured crystals, easily soluble in dilute hydrochloric acid or alkalis. The colouring matters give reddish-violet to blue shades on chrome mordants, according to the diamine employed, and are said to be fast to soap and fulling.—T. A. L.

**Improvements in the Manufacture of Auramine.** J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 6249, March 23, 1893.

THIS is an extension of Eng. Pat. 12,549 of 1889 (this Journal, 1890, 498) and of Eng. Pat. 16,666 of 1890 (this Journal, 1891, 762). The methods there given describe the preparation of auramine from tetramethyl-diamido-diphenyl-methane or its derivatives, the corresponding hydrol and thio-hydrol, by treating them with sulphur and ammonia. It has now been discovered that tetramethyl-diamido-diphenyl dimethyl-methane can also be converted into auramine by treating it with sulphur and ammonia, under suitable conditions. This compound can be obtained by condensing acetone with dimethylaniline (Ber. 12, 813; 6, 345). The following quantities are given for the preparation of auramine according to the present invention:—About 14 kilos. of tetra-methyl-diamido-diphenyl-dimethyl-methane and 6 kilos. of sulphur are mixed with 120 kilos. of salt and 7 kilos. of ammonium chloride, and a stream of ammonia gas is passed through the mixture for eight hours at 175° C. The melt is first washed with cold water to dissolve away the salt and ammonium chloride, and is then dissolved in water at 70° C., filtered, salted out, pressed, and dried.—T. A. L.

**Manufacture of New Colouring Matters.** J. C. L. Dand, D. E. Huguenin, and A. J. J. d'Andron, St. Fons, Rhone, France. Eng. Pat. 24,892, December 23, 1893. Date under International Convention, July 4, 1893.

THESE colouring matters are obtained by the action of phenols and their derivatives on the oxazines and gallo-cyanines, and subsequent oxidation and sulphonation of

the substances produced. The colouring matters obtained are bodies soluble in alkalis, giving blue to violet solutions, and forming violet blue lakes with metallic mordants. 10 kilos. of gall-cyanine, obtained by condensing gallic acid with nitroso-dimethylaniline hydrochloride, 15 kilos. of resorcinol, 20 litres of water, and 90 kilos. of commercial hydrochloric acid are heated together on the water-bath until the bluish-violet coloration has disappeared and greenish-yellow crystals have separated. After diluting with water and washing free from acid, the green substance is oxidised with air in an alkaline solution, giving a violet-blue colouring matter after precipitation with hydrochloric acid much bluer than the original gallo-cyanine. This can then be sulphonated in the usual manner. The condensation product may also be sulphonated by dissolving in sulphuric acid, and subsequently oxidised by adding ferric oxide; or sulphuric acid may be used alone to act as both condensing and oxidising agent, as at 100° C. it acts as an oxidiser. Whichever method be employed, the product of the reaction is precipitated by water and washed free from sulphuric acid. If higher sulphonic acids have been formed it may be necessary to separate them as calcium salts, as these acids are soluble in water.—T. A. L.

and highly polished. When of sufficient thickness, the film is transferred on to the permanent fabric by passing it and the cloth face to face between rollers.—F. H. L.

*Improved Manufacture of Detergent for Washing and Cleansing Dirty Linen.* Annalie Gross, Szederjes, Austro-Hungary. Eng. Pat. 23,398, December 5, 1893.

## VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

*Note on the Different Theories relating to Dyeing.*

Leo. Vignon. Bull. Soc. Ind. Mulhouse, 1893, 407—410.

THE absorbing power that textiles, hide, and metallic oxides exercise on colouring matters, has been attributed to different causes, and generally explained by the mechanical and chemical theories; the former limiting its facts to that of absorption, whatever its cause; the latter explaining the production of dyeing by chemical agencies.

It has been stated that in the phenomena observed in dyeing, no chemical combination ensues between the coloring matter and the textile; the dyed result does not present the essential characters of a chemical compound. It is also stated that the colouring matters are not combined with the textiles, but in some way dissolved in them, this opinion suggesting the substitution for the term "absorption" by that of "solution," a view standing midway between the existing chemical and mechanical theories.

The author is of opinion that dyeing may be considered as involving chemical phenomena, in which dissociation occurs, and that dyeing only takes place when certain chemical functions are exerted by the absorbing body and the colouring matter; moreover, there are two facts not to be lost sight of, namely, the high molecular weight of the textile in comparison with the colouring matter, and dissociation. Although the molecular weight of the textiles is not known, there is every indication of its being very high, and it is difficult to conceive that a molecule weighing 4,000 units fixes 1, 2, . . . ,  $n$  molecules of a body, the molecular weight of which is relatively low; it is difficult to establish the law of definite proportions.

The phenomena of dissociation are frequently produced by the action of solvents; for example, aluminium chloride, carbonates, borates, alums, and ammoniacal salts are dissociated at the ordinary temperature by means of water; even in contact with absolute alcohol, hypochlorite of calcium is decomposed, chloride of calcium dissolving and lime remaining in suspension, this phenomenon being quite analogous to that of the coloration of alcohol by a magenta-dyed fabric.

In every case of dyeing there is inferred a system consisting of three elements, the absorbent, the colouring matter, and the solvent; and between these three a state of equilibrium is arrived at, determined by the chemical force and the condition of dissociation of the system; it may appear then that the law of definite proportions is not applicable to the phenomena of dyeing.

In the author's opinion the great majority of dyeing phenomena are of a chemical nature, chemical action sufficing to explain them, especially when we also consider the part that dissociation plays.

The general character of dyed substances is marked by the formation of a chemical compound, more or less dissociated by different solvents (this Journal, 1894, 120—127).—W. R.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

### PATENTS.

*A New or Improved Process for the Treatment of Textile Vegetable Fibres, and Apparatus connected therewith.* A. F. B. Gomess, London. Eng. Pat. 18,358, October 13, 1892.

THE invention relates to the preparation of textile fibres from the cortex of plants, particularly those of the Urtica family. Lime is first removed by steeping in a cold solution of sodium thiosulphate, whereby soluble calcium thiosulphate is formed. The epidermis is also deoxidised and rendered more soluble. A thorough washing follows, which finally removes the calcium compound. The fibre is next boiled with caustic soda and zinc dust, and again washed, then soaked in a dilute solution of sodium hypochlorite and hydrochloric acid, washed, and passed through weak ammonia to remove any traces of chlorine. Finally, it is washed and boiled with soap.

The apparatus employed in some instances consists of a hollow revolving drum, inside which a number of pegs are fixed, and into which hot air can be passed.—R. B. B.

*Improvements in or relating to Open Soaping, Washing, Boiling, and other similar Machines for Operating upon Textile Fabrics.* C. L. Jackson, Bolton, and E. W. Hunt, Manchester. Eng. Pat. 209, January 16, 1893.

THREE or more triangular beaters of wood or metal are arranged in such a manner above the level of the liquid in the washing machine that the cloth is struck and shaken three times during each revolution, the effect being as if it were suddenly pulled lengthwise between the top and bottom guiding rollers. These beaters remove hard and thick substances from the cloth.

The machines are charged with soap solution or other liquid by a pipe entering at the bottom of the vessel, and the liquid overflows at the top. The substances beaten out from the cloth are thus carried away at once, and precipitation is prevented.—R. B. B.

*Improvements in the Manufacture of Rubber coated Waterproof Fabrics.* W. Abbott and W. R. Wilks, London. Eng. Pat. 6769, March 30, 1893.

A COATING of rubber is prepared on a temporary support, consisting, for instance, of prepared rubber cloth, vulcanised

*Report on the Previous Note.* M. A. Rosenstiehl. Bull. Soc. Ind. Mulhouse, 1893, 411.

THE forces contributing to the dyeing process are of two kinds—

1. *Adherence or cohesion*, and this is always present. It is the mere attraction of matter by matter.

2. Chemical attraction, which often happens, but is not indispensable.

Neither the chemical nor mechanical theory by itself explains dyeing satisfactorily. It may be defined as the operation which consists in covering the textile fibre with a perfectly adherent layer of a coloured substance, which often is a combination of a portion of the substance of the fibre with a colouring matter.—W. R.

## PATENTS.

*Improved Detergent Compound or Preparation for the Washing or Scouring of Textile Fabrics or other Articles.* W. Brothers, Rawtenstall, Lancashire. Eng. Pat. 6123, March 22, 1893.

See under XII., page 260.

*Improvements in the Method of and Means employed for Bleaching, Dyeing, and otherwise treating Flax, Hemp, and other Fibres.* A. McMeekin, Doagh, Ireland. Eng. Pat. 6600, March 29, 1893.

THE flax &c. in the form of "rove" is wound on perforated bobbins or tubes. The bleaching or other liquid, or hot air, is forced by pressure into the centre of the bobbins, and can find no other outlet save the perforations in the bobbins, through which it passes, and thence through the fibre, whereby the latter becomes thoroughly penetrated.

—R. B. B.

*Improvements in Dyeing Machines.* L. Weldon, Amsterdam, New York, U.S.A. Eng. Pat. 21,185, November 7, 1893.

THE machine described is adapted for dyeing loose wool or cotton, and consists of an open-work cage divided into two or more compartments, revolving in the dye liquor in such a manner that the fibre is alternately immersed in the dye bath and carried out of it. The particular improvement here is an arrangement whereby the rolling and consequent matting of the fibre during the revolution of the cage is minimised. In each compartment longitudinal ribs and "horns" extend from the axis of the cage part way towards its periphery. Opposite to these horns, and attached to the inside of the cage, are hooks, capable of swinging freely in one direction. The combination of "horns" and hooks is so arranged that the fibre in passing from one side of the compartment to the other, as it must do when the cage is revolving, does so in a gradual and gentle manner, thereby decreasing the matting effect, and increasing the evenness of dyeing.—R. B. B.

## VII—ACIDS, ALKALIS, AND SALTS.

*Production of Chemically Pure Caustic Soda and Hydrogen from Sodium.* M. Rosenfeld. J. Prakt. Chem. 48, 599—601.

THE explosions which occur when water and sodium interact, are attributed by the author to the formation within the metal of sodium hydride, which afterwards dissociates suddenly and violently. As this compound can only be produced when an atmosphere of hydrogen surrounds the sodium, the author has been led to try the action of a current of steam on sodium, the hydrogen being removed as it is formed. He finds that the reaction proceeds very smoothly without any tendency to explosion, and that pure solid caustic soda and hydrogen free from oxygen may easily be obtained in this way. The apparatus he uses consists of an iron crucible with two side tubes (for the admission of steam and the delivery of hydrogen, respectively) and a lid fastened down by means of a stirrup and screw. The caustic soda obtained always contains some finely-divided iron, probably from the formation of a sodium-iron alloy in the first stages of the reaction.—J. W.

*The Use of Electrical Heat for the Concentration of Sulphuric Acid.* A. H. Bacherer. Chem. Zeit. 17, 1597—1598.

IN order to produce 100 kilos. of 66° vitriol, 117 kilos. of 60° acid are requisite; taking this as having the temperature 18° C. to begin with, and the concentrated acid as being at 330° C. to end with, and further assuming the specific heat of the acid to be 0.33, the heat consumption during the heating up and evaporation will be as follows:—

	Calories.
1. Heating 60° acid from 18° to 330° C. ....	16,296
2. Heating acid, evaporation of 17 kilos. water, ..	12,283
3. Heat evolution during union of 60° acid with 1½ H <sub>2</sub> O, forming 66° acid, .....	10,000
	<hr/> 32,679

Hence  $32679 \div 4.2 \times 10^3$  Watts per second are required, or  $\frac{32679 \times 4.2 \times 10^3}{736 \times 3600} = 44.2$  horse-power per hour; or, allowing for loss of heat by radiation, &c., from the glass retorts, about 50 horse-power per hour. Admitting the practical cost of the current to be 0.04 mark per hour horse-power (0.01 shilling), the cost of concentrating one ton (1,000 kilos.) will be 20 marks (about 1*l.*).

IN order to calculate the dimensions of a platinum wire capable of furnishing the requisite heat, it is assumed that the mean temperature of the wire is 150° C. higher than that of the acid, i.e., is 480° C.; this amounts to supposing that with this excess of temperature of metal over that of acid, the rate of passage of heat into the fluid is just as rapid as its rate of generation by the current. If the difference of potential between the ends of the wire be 5 volts, a current of 364 amperes will develop in a wire 0.5 cm. diameter and 77 cm. long, 2.4 electrical units; hence, in the course of 5 hours, 12 units are produced, competent to concentrate 24 kilos. of 66° acid (starting at 60°) in a vessel suitably jacketed to minimise loss by conduction, &c. Whether, however, it will prove cheaper in practice to use a weaker current for a proportionately longer time, or *vice versa*, is a matter which cannot be decided *a priori* without actual trial. The calculations indicate at least the probability that electrically generated heat may be economically employed in the concentration of oil of vitriol, and that the process would not involve any special technical difficulty, but on the other hand would in various ways be more convenient than the methods now in ordinary use.—C. R. A. W.

*The Inertness of Quicklime. II. The Interaction of Chlorine and Lime.* V. H. Veley. Proc. Chem. Soc. 1893, [128], 209.

THE author has ascertained by synthetical and analytical methods that no appreciable action takes place between dry chlorine and quicklime below 300°; above this temperature, a partial displacement of oxygen is effected by the chlorine; the interaction is thus analogous to that of baryta and chlorine, not specially dried, and at ordinary temperatures.

#### PATENTS.

*Improvements in the Manufacture of Alkali, and in Apparatus therefor.* J. Hargreaves, Farworth-in-Widnes, and T. Bird, Cressington, Liverpool. Eng. Pat. 18,871, October 21, 1892.

ACCORDING to these improvements, relating in part to Eng. Pat. 18,039, 1892, alkali is obtained by electrolysis from chloride of sodium solution. The anode compartment, only containing the electrolyte, is bounded by a porous partition, in contact with which, on the outer side, or in proximity thereto, is placed a permeable cathode of iron gauze or perforated cathode, from which the alkali is washed off as electrolysis proceeds by steam or vapour, or spray or jet of liquid led on to it through a second containing chamber or tank, in which the soda is collected as solution at the bottom, but which does not contain the electrolyte, except such little as may pass from the anode compartment by filtration through the diaphragm, or which may be introduced in the form of steam or spray.

—J. C. R.

*Improvements in the Method of and Apparatus for the Electrolytical Separation of the Bases of Salts and of Compounds of the Same from Saline Solutions.* C. T. J. Vautin. Eng. Pat. 2267, February 1, 1893.

See under XI., page 256.

*Improvements in the Utilisation of Chlorides of Sodium and Potassium for the Obtainment of Useful Products.* T. Parker and A. E. Robinson, Wolverhampton. Eng. Pat. 1920, March 7, 1893.

THESE improvements relate to a method of removing or fixing caustic alkali resulting from electrolytic action from the sphere of such action, either as the caustic alkali is liberated, or from time to time before it accumulates in sufficient quantity to interfere in a material degree with the efficiency of the further electro-chemical reaction. The method or process of removal consists in combining with the alkali, some fatty acid, such as oleic, stearic, or margaric, either in the cathode compartment or separate tank to which the alkali is transferred. The compound thus formed, owing to its lower specific gravity than the electrolyte, rises to the surface and can be removed. The fatty acid may be added in the form of fat or oil, such as tallow, olive oil, cotton-seed oil, palm oil, &c. The soap

compound made may be used as soap, or treated with carbon dioxide, and the alkali converted into carbonate, undecomposed electrolyte being returned to the tanks.—J. C. R.

*An Improved Process of Manufacturing Bleaching Solutions by Electrolysis.* A. J. Boulton, London. From O. Knocher and F. Gebauer, Charlottenburg, Germany. Eng. Pat. 3578, March 17, 1893.

THESE inventors set out advantages in the electrolytic decomposition of a solution of common salt for the production of hypochlorites for bleaching purposes, from adding lime to the solution, which is not such a good conductor as hypochlorite of soda, nor its hypochlorite so readily reduced by hydrogen at the cathode; but in the present invention their claim is for a process of manufacturing a bleaching solution, consisting in subjecting a solution of mineral salt, without the employment of diaphragms, to electrolysis with a density of current of from 300 to 800 amperes per square metre of electrode surface, the extent to which the lye is made richer in active chlorine being determined by correspondingly regulating the rise of temperature, while, conversely, by maintaining a uniform rise of temperature an equally uniform percentage of active chlorine may be secured in the lye produced. A 10 per cent. solution of salt being preferred, the quantity which passes through the electrolytic tank in a given time may be said to regulate both temperature and percentage of available chlorine in the body of liquid treated, and may be made guides for practical work without chemical analysis; at least, such seems to be the idea of these inventors, who give a short table of results, and refer to Eng. Pat. 20,214, 1892 (this Journal, 1893, 933).—J. C. R.

*Improvements in the Manufacture of Nitric Acid.* M. Prentice, Woodfield, Suffolk. Eng. Pat. 6960, April 4, 1893.

THE object of the invention is to manufacture nitric acid by a continuous process. A still or vessel is provided, having an inlet for the nitrate and acid, and a siphon or other outlet for the fluid mixture, as well as an outlet for taking off the nitric acid as it distils. The still may be divided into separate compartments, these communicating with each other from below. The inventor does not limit himself to any particular construction of still.—E. S.

*Improvements connected with the Manufacture of Nitric Acid, Muric Acid, or the like, where Sulphuric Acid is employed, and of Superphosphate of Lime.* M. Prentice, Woodfield, Suffolk. Eng. Pat. 8902, May 3, 1893.

IN the manufacture of nitric or hydrochloric acid or the like, wherein sulphuric acid is used, the manufacture is facilitated by using the sulphuric acid in large excess. The available acid left in the acid sodium or other sulphate formed, is then employed in the preparation of superphosphate, by running off the acid product and mixing it with calcium phosphate.—E. S.

*Process for the Production of Alkali Cyanides.* W. Siepermann, Elberfeld, Germany. Eng. Pat. 13,754, July 15, 1893.

ALKALINE cyanides are obtained by heating alkaline carbonates, or alkaline compounds convertible into carbonates in the process, with fuel, aided by a hot blast. Pieces of wood or coke fuel may be saturated by a solution of the alkali carbonate and dried; or the materials may be mingled, the proportions being about one part of the carbonate to two or three parts of the fuel. The charge is introduced through a hopper box with double closure, to prevent escape of poisonous gases; but when a nitrate or nitrite is used instead of a carbonate, it is run in a fused state through a funnel into a pipe connecting one of the heat-regenerating chambers to the furnace, so that the hot blast projects the salt in

spray on to the fuel, to which a small addition of alkaline carbonate has been made. The reacting chamber or furnace containing the charge has a floor inclined towards the tapping hole, and a hearth extended in an opposite direction, joining a pipe which carries the gases and vapour of the cyanide into a cooler furnished with spiral wings or plates, wherein the alkaline cyanide settles as powder. The cooler is a large iron vessel mounted on flange wheels running on rails for convenience of replacement. From the cooler the gases pass into a coke-scrubber, where they are washed free from alkali compounds, and thence to one of the two regenerators to be burnt. "The residual cyano compounds contained in the gases are obtained in the form of red or yellow prussiate of potash by washing with water to which iron salts have been added."—E. S.

*Improvements in Apparatus and Furnaces for Concentrating Sulphuric Acid and other Liquids.* J. Bradbury, Manchester. Eng. Pat. 22,327, November 22, 1893.

A SERIES of evaporating vessels of lead or other suitable metal, earthenware, or glass, is set upon a metal plate, which plate, as well as the chambers containing the vessels, are heated by flues from a fireplace set at the opposite end of the furnace to that at which the acid to be concentrated enters. The vessels are at one uniform height, and discharge one into another, either by a spout or by a siphon tube reaching nearly to the bottom. If a spout be used, the overflow is into a tube bent horizontally at the lower end close to the bottom, so as to ensure thorough mixing of the lighter entering acid with that more concentrated in the vessel. Metallic shields, made in halves, and secured by bolts passing through lugs, are provided to protect the evaporating vessels from the heat; but these may be dispensed with in the cooler part of the furnace. A closed-in space above the evaporators is connected by suitable openings to a pipe conveying the vapour and fumes given off to a stack. An acid tank, heated by flues, is set over the chamber containing the series of vessels, and supplies by a tap or valve a small box, from which the acid is led to the tube delivering at the bottom of the first vessel of the series. As this vessel fills, it discharges through its spout into the tube of the next vessel, and so on through the series. But if the siphon arrangement be used, the acid tank is placed at the side of the furnace, nearly level with the evaporating vessels, and is supplied with a well, into which the longer limb of a siphon dips, the other limb entering the first vessel of the series. Another siphon tube, with limbs of equal length, connects this vessel with the next, and so throughout. When the acid in the tank (which is fed through a pipe with tap) reaches the level of the tube connecting the limbs of the siphon, the vessels are charged with acid in succession through the tubes. The vessels may be emptied from another corresponding acid tank forming the terminus, by opening a tap at the bottom of the well, and so running out the acid. The conduct of the process may be modified in various ways.—E. S.

*Improvements in Apparatus for Electrolytically Producing Soda and Chlorine.* H. Lake and Co., London. From the Union Chemical Company, New York, U.S.A. Eng. Pat. 23,436, December 5, 1893.

See under XI., page 257.

*Improved Process and Apparatus for Dissociating Soluble Salts by Electrolysis.* H. Haddon and Co., London. From H. S. Blackmore, Mount Vernon, New York, U.S.A. Eng. Pat. 23,913, December 12, 1893.

See under XI., page 257.

*Improvements in the Concentration or Vaporisation of Sulphuric and Acetic Acids, and in Apparatus therefor.* A. J. Bault, London. From S. C. Penchen and P. Clarke, Toronto, Canada. Eng. Pat. 24,739, December 23, 1893.

THE objects of the process are, to precipitate impurities from the sulphuric or acetic acid treated, and to effect the concentration or vaporisation of the acid, as may be desired, and it is stated that "these objects are accomplished by passing through the acid an electric current from acid-proof electrodes of high electrical resistance, either held stationary or arranged so that they may be revolved in the liquid," the necessary heat being produced within the liquid by the electrical resistance. The sulphuric acid to be concentrated (for instance) may be contained in a glass retort within which is a porcelain stand supporting two carbon electrodes connected to a dynamo or battery by platinum wires. The current is preferably of low voltage. If the acid is to be distilled, the retort is connected to a suitable condenser, and a stronger current in amperes is required. An apparatus is shown, in which a hollow revolving shaft carrying arms with electrodes at their extremities is fitted within a close vessel containing the acid to be treated. Insulated wires are connected to the electrodes, and to metal terminals at the ends of the shaft, details of the arrangements being shown and described. Alternatively, the shaft carrying the arms with electrodes, may be rigidly fixed.—E. S.

## VIII.—GLASS, POTTERY, AND ENAMELS.

### PATENT.

*An Improved System and Apparatus for Removing Impurities from and Refining China Clay.* W. W. R. Nicholls, W. Nicholls, and F. H. Nicholls, St. Austell. Eng. Pat. 19,699, October 19, 1893.

EACH "set" of the elutriating apparatus used for washing china clay is provided with "mica traps" operated by eccentrics on a lever disposed at right angles to the set and actuated by a handle turning in a quadrant with locking holes and pins so that the traps may be set at any desired angle. The purified clay passes into a refiner with a wire-gauze covering kept clean by revolving brushes, which are themselves cleansed by a jet of water at one part of their revolution. The brushes are driven from a water-wheel hung in the launder conveying the stream of purified clay, suspended in water, to the settling pit.

—B. B.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*The Effect of the Addition of Gypsum to Portland Cement.* Schott. Thonind. Zeit. 1893, 17, 926.

THE author has investigated Michaelis' explanation of the accelerating action of the addition of gypsum to Portland cement as being due to the formation of a double salt ( $\text{Al}_2\text{O}_3, 3\text{CaO} + 3\text{CaSO}_4$ ), and has experimented with cements made from a mixture corresponding to a formula of  $2\text{CaO}, \text{SiO}_2$ , and from a mixture of marble and kaolin. His results leave it uncertain whether the accelerating action is due to the formation of this double salt or whether to the crystallisation of calcium hydrate.

—J. G. W.

*The Characteristics of Portland Cement.* R. Fresenius and W. Fresenius. *Zeits. Anal. Chem.* **32**, 433—445.

This article is a continuation and amplification of the authors' communication published in 1884 "On the Detection of Adulterations in Portland Cement" (*Zeits. Anal. Chem.* **23**, 175; this Journal, 1884, 373), and gives the results of investigations undertaken, some three years ago, on behalf of the Society of German Portland Cement Makers. One of the objections raised to the figures given in their first communication was that they were obtained from too small a number of samples, and another was that these samples were not representative of actual commercial cements. In a second paper published in 1885, the authors replied to this criticism (*Zeits. Anal. Chem.* **24**, 66; this Journal, 1885, 349), and stated their conclusion that any further investigation of the subject was unnecessary until a more exact definition of what constituted "Portland cement" had been formulated and become recognised. In 1885, at a general meeting of cement makers, a definition or specification of what constituted "Portland cement" was unanimously adopted, and in 1888 the Society of German Portland Cement Makers was founded, and adopted the following resolutions as a basis:—

"The undersigned members of the Society of German Portland Cement Makers bind themselves to place on the market under the designation 'Portland cement,' only one kind of commodity, which shall be made by burning to a frit an intimate mixture of materials containing lime and clay as their essential constituents, and grinding the product to the fineness of meal.

"Any product made in any other way than the above, or to which any foreign matter has been added either during the burning or afterwards, shall not be recognised by them as 'Portland cement,' and the sale of such under the designation 'Portland cement' shall be held to be a deception practised on the buyer.

"This provision does not refer to small additions made to regulate the time required for the 'setting' of the Portland cement, which additions shall be permissible to the extent of 2 per cent."

The establishment of this clearer definition of "Portland cement" made it possible and desirable to redetermine the limits of the constituents found in various qualities of Portland cement, and especially was an extension of the work upon the determination of the contents of magnesia needful, because, in the interval, the signification of the contents of magnesia had become a question of first interest.

Practical experience of the durability of cement used in various public works has shown that less than 3 per cent. of magnesia was harmless, but that appreciably higher amounts than this produced very serious evils. Now, since the adopted definition excludes Portland cements containing large amounts of magnesia, those containing small quantities are not excluded by it, and therefore it became necessary to decide what amount of magnesia should be permissible in the sense of this definition. For this purpose a determination of the average amount of magnesia contained in the Portland cements manufactured at the time in Germany was undertaken.

The samples were supplied by the executive of the Society, which is also responsible for their authenticity, and were for the most part taken from cements actually in commerce, and not, as in the case of the authors' first investigations, from cements chiefly derived from the makers' works. On the former occasion, some English and French cements were examined, but in this investigation they were all samples of German makes. Both big and little works are represented, and the 25 samples examined represent a total of 5,750,000 casks of cement per annum, the total German output in 1889 being 7,950,000 casks.

The lines of the present investigation differ from those of the first, by the specific gravity in the calcined state and the contents of magnesia being now determined, whilst the determinations of the amount of acid used up on shaking with the cement, and of the capacity for absorbing carbonic acid, are omitted as being unnecessary.

The results obtained are given in the following table:—

Mark.	Specific Gravity.		Loss on Calcination.	Alkalinity of the Aqueous Solution of 0.5 grm., stated in Decinormal Acid.	Magnes. Potassium-Permanganate reduced by 1 grm.	Percentage of Magnesia.	Strength.		Fineness.

Slow setting.

Quick setting.

From this table it will be seen that the following maxima and minima have been obtained.

The specific gravity of the uncalcined cement lies between 3.011 and 3.144.

The specific gravity of the calcined cement lies between 3.118 and 3.234.

The loss on calcination is found to be from 0.79 to 3.37 per cent.

The alkalinity of the aqueous solution of 0.5 grm. of cement lies between 3.00 and 7.20 cc. of  $\frac{1}{10}$  normal acid.

The potassium permanganate reduced by 1 grm. of the cement lies between 0.105 mgrm. and 2.19 mgrm.

The percentage of magnesia lies between 0.35 and 3.064.

Comparing these numbers with those obtained in 1884, some slight differences are noticeable.

To begin with the least important, the potassium permanganate reduced is less in many cases than was formerly found.

The alkalinity in several cases does not reach the lowest limit of the previous tests, but this is unimportant, as it is only when the upper limit is exceeded that this determination has significance. In these samples the maximum is lower than the maximum of the earlier tests, with the exception of sample No. 1, which exceeds the maximum considerably.

The loss on heating to redness is generally higher than in the former tests, which is no doubt explained by the fact that the samples were taken from cements that in many cases had been stored some time, and were not direct from the works, as in the earlier tests.

The most noteworthy difference is in the lower results that have this time been found in the specific gravities of the uncalcined cements. With regard to this point also it may be mentioned that experience has shown that the specific gravity of cement falls after storing.

With regard to the specific gravity of the calcined cement, this seems to be greater than the specific gravity of the uncalcined cement, according as the loss in heating increases, but no fixed relation between the three can be drawn from the results obtained.

The maximum contents of magnesia is 3 per cent., and this result agrees with the percentage declared in 1888 by the German Portland cement makers, to be quite harmless to the qualities of Portland cement.

Cement No. 1 requires special notice, as it gave the greatest alkalinity, and the greatest loss on heating, whilst its specific gravity in the uncalcined state was the lowest of all the samples examined. On comparison of this cement with another from the same firm, which only showed an alkalinity of 3.40 cc., and 2.09 per cent. of loss on heating, and also from a consideration of its high specific gravity after calcination, and of its strength, the authors are left in no doubt that the cement is not abnormal, but that these variations from the respective values found in the case of the other samples of cement are due to the length of time that

cement No. 1 had been stored. By taking the low specific gravity and the high alkalinity of this cement as limits, the authors think they have provided sufficiently against any cement which happens to have been stored a long time being mistaken for an abnormal cement.

From the results obtained in their first investigation, and from those now obtained, the authors consider the following to be limiting values characteristic of Portland cement:—

1. Specific gravity in the uncalcined state, not less than 3.00.
2. Specific gravity in the calcined state, not less than 3.12.
3. Loss on calcination, not more than 3.4 per cent.
4. Alkalinity of the aqueous solution of 0.5 grm. of cement, not more than 7.2 cc. of decinormal acid.
5. Potassium permanganate reduced by 1 grm. of cement, not more than 2.8 mgrms.
6. Magnesia in the cement, not more than 3 per cent.

The loss on calcination was determined by heating portions of 10 grms. of the cement to redness, in a covered platinum dish for at least one hour over a large gas flame. (Maste's burner). It was then kept in a desiccator, and afterwards used for determining the specific gravity in the calcined state, for which purpose Schumann's apparatus was used. The estimation of the magnesia was made by dissolving about 2 grms. of the cement in hydrochloric acid, evaporating to dryness to render silica insoluble, filtering, and then precipitating the iron and alumina from the filtrate by ammonia. This precipitate was redissolved and again precipitated by ammonia, and from the united filtrates the lime was separated by ammonium oxalate, this precipitate being also redissolved and reprecipitated. The filtrate now obtained was evaporated to dryness, the residue calcined to expel ammonia salts, and the remaining substance dissolved in dilute hydrochloric acid. Any traces of iron, alumina, and lime still remaining were then removed by further treatment with ammonia and ammonium oxalate, and the magnesia finally precipitated as ammonium-magnesium phosphate and weighed as magnesium pyrophosphate. An attempt to shorten the method by a modification doing away with some of the filtrations had to be abandoned, as the results obtained were not sufficiently exact.

Should a cement give results that fall outside any of the limits above specified, it must be more particularly examined with a view of finding if foreign matter be present, or if it be a sample of under-burnt cement. In the latter case its quality can be further judged off by the usual mechanical tests.

The authors, in conclusion, give the results of some investigations made by them in 1885, on—

1. The behaviour of strongly-burnt cements when tested by their method.
2. On the influence on their method of manganese dioxide (manganese ore) mixed with cement.

3. On the behaviour of some other substances of interest in this connection when tested by their method.

In these tests the magnesia and the specific gravity in the calcined state were not determined.

1. Experiments with strongly-burnt cements made of the same raw materials.

The results obtained are given in the following table:—

Mark.	Specific Gravity.	Loss on Heating.	Alkalinity of Aqueous Solution of 0.5 Grm. Ce. in Normal Acid.	Ce. Normal Acid consumed by 1 Grm. of Cement.	Mgms. Potassium Permanganate reduced by 1 Grm.	Mgms. of Carbonic Acid absorbed by 3 Grms.

Slightly fritted.....	2.92	5.39	0.3	18.1	0.62	31.1
C. Strongly fritted.....	3.00	2.36	4.3	21.0	0.65	15.7
Very strongly fritted	3.19	0.21	2.7	18.9	0.97	1.9

These samples were from three different works, A., B., and C. respectively. From the above table it may be seen that there is a marked difference between the under-burnt and the over-burnt cements, as compared with the "slightly fritted" and the "strongly fritted" made of the same raw materials. But there appear to be some discrepancies on comparing the products of one works with those of the others, but whether this is due to differences in the materials used, or to some different understanding of the term "fritting," the authors are unable to say.

2. The effect of mixing manganese with the cement was investigated, because it was suggested that the value of the test with potassium permanganate, which is important as an

indication of adulteration with slagmeal, would be interfered with, supposing both slagmeal and manganese ore were mixed with the cement. The results show that, although a somewhat less quantity of permanganate is reduced when manganese dioxide has been mixed with Portland cement containing slagmeal, nevertheless in order to neutralise the reducing effect of the slagmeal, the quantity of manganese ore must be so large as to be easily detected by the dark colour of the cement and the chlorine evolved on dissolving it in hydrochloric acid.

3. Three samples of Roman cement, one sample of coal clinker, and one sample of Pozzuolana were tested by the authors' process and gave the following results:—

Mark.	Specific Gravity.	Loss on Heating.	Alkalinity of Aqueous Solution of 0.5 Grm. = Ce. in Normal Acid.	Ce. Normal Acid used up by 1 Grm. of Substance.	Mgms. of Potassium Permanganate reduced by 1 Grm.	Mgms. Carbonic Acid absorbed by 3 Grms.
		Per Cent.				
Roman cement, A.....	3.08	8.44	1.70	20.55	..	1.7
" B.....	2.80	14.28	6.30	15.45	..	4.1

—H. S. P.

#### PATENTS.

*Manufacture of Artificial Marbles.* F. Grand' Montagne, Brussels, Belgium. Eng. Pat. 1582, January 24, 1893.

MIXTURES suitable for the production of artificial stones having a basis of powdered marble or other stone, and Keen's cement, or Portland cement, are mixed with zinc chloride and zinc oxide, or with magnesium chloride, and separate portions, tinted with as many different colours as may be required, are dashed on to the bottom of a mould so as to produce a veined pattern which after filling up the mould, constitutes the ornamental surface of the artificial marble. The block may be veined throughout by the insertion and subsequent withdrawal of silk threads or wires covered with silk soaked in appropriate colours. The product may be polished by treatment with a hardening

liquid, e.g., zinc chloride followed by polishing with a mixture of alcohol 75 per cent., oil 5 per cent., plaster 5 per cent., white gum lac 5 per cent., turpentine 5 per cent., and yellow wax 5 per cent.—B. B.

*Improvements in the Manufacture of Cement.* W. Webster, Blackheath. Eng. Pat. 3106, February 11, 1893.

This patent is a development of Eng. Pat. 11,765, 1892 (this Journal, 1893, 604), in which sewage sludge is utilised in the manufacture of cement. In addition to or in place of the sludge, the patentee claims the use of the ash of waste vegetable matter or of coal or coke, which is mixed with the clay and chalk used in the manufacture of the cement,

in proportion depending upon the composition of the clay. The quantity of ash added is from 1–5 per cent. of the whole cement mixture.—B. B.

*Improvements in the Utilisation, in the Manufacture of Portland Cement, of Precipitated Carbonate of Lime forming Waste Products from Chemical Works and in Apparatus for Employment thereon.* J. Hill, Wolverhampton. Eng. Pat. 5132, March 9, 1893.

The process is designed to mix precipitated carbonate of lime, such as that recovered in Chance's sulphur recovery process, with clay for the production of Portland cement, with the use of less water than is customary, to diminish the cost of drying. The clay is fed through a hopper into a barrel-shaped vessel in which a shaft having wedge-shaped beaters keyed to it, revolves. The disintegration of the clay is aided by blowing in steam during the process. The precipitated carbonate of lime is then added and incorporation continued until the material is homogeneous, when it is discharged through a man-hole at the bottom of the barrel-shaped vessel and is dried and burnt in the usual way. Economy of water, and therefore saving in cost of drying, are claimed for this process and apparatus.—B. B.

*Improvements in the Manufacture of Artificial Stone, Preservative Paint and other Analogous Materials.* L. Grote, Landberg-on-Lech, Germany. Eng. Pat. 17,142, September 12, 1893.

VARIOUS recipes are given containing magnesium chloride, magnesia, calcium plumbate, water and such filling materials as slagwood, sand, gravel, clay, wood, wood-pulp, wood-shavings, sawdust, paper, vegetable and animal fibres, resinous and fatty matters, are patented, the ingredients and their proportions being varied according to the character of the composition required, which may be used for building stone, insulating material, plaster, or paint.—B. B.

## X.—METALLURGY.

*Preparation of Metallic Lithium.* M. Gnutz. Comptes rend. 1893, 117, 732–733.

The author finds that the best yield of lithium is obtained when the temperature at which electrolysis occurs is low. In order to assist the fusion of lithium chloride it is mixed with an equal weight of potassium chloride, such a mixture melting at about 450° C. The positive electrode is of carbon and 8 mm. in diameter, and the negative electrode is a rod of iron 3–4 mm. in diameter, and enclosed in a glass tube 20 mm. in diameter. On passing a current of 10 ampères and of an electro-motive force of 20 volts, electrolysis rapidly proceeds and the lithium becomes deposited within the glass tube.

The metal thus prepared contains about 1–2 per cent. of potassium, and is sufficiently pure for most purposes.

—A. K. M.

*The Action of Gaseous Hydrochloric Acid and Oxygen on the Platinum Metals.* W. L. Dudley. J. Amer. Chem. Soc. 1893, 15, 272–274.

THE author observed that finely-divided platinum sponge on being washed with hydrochloric acid gave evidence of solubility. On moistening platinum black on a filter with dilute hydrochloric acid he found that the paper became yellow after a few hours, and on washing, the filtrate contained platinum chloride. On continuing the washing even with hydrochloric acid, platinum ceased to be present in the filtrate, but on standing exposed to air the attack of the platinum again became manifest. The action of air and hydrochloric acid on platinum sponge was similar to, but

less marked than, that of the same substances on platinum black. When dried HCl and air were used similar results were noted; the action of HCl and oxygen dried and moist was sensibly the same, both at ordinary temperatures and at 100° C.

It has already been shown that finely-divided palladium dissolves by the action of hydrochloric acid and oxygen or air (Fischer, Schw. 51, 132; Pogg. 71, 131).

The author experimented with iridium, rhodium, ruthenium, and osmium and obtained like results. The action on ruthenium and osmium was greatly increased on heating, especially to 250° C. or more, and the action was comparatively rapid, the chlorides subliming. The metals used in these experiments were not specially purified, but bought of good makers as "pure"—B. B.

*An Examination of the Ordinary Methods for the Estimation of Carbon in Iron.* A. Ledebur. Chem. Zeit. Rep. 17, 1893, 259.

See under XXIII., page 281.

*Estimation of Chromium in Chromium Steel and Chromium Ore.* J. Speller and S. Kalman. Chem. Zeit. 17, 1893, 1360 and 1412.

See under XXIII., page 281.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

*The Use of Electrical Heat for Concentrating Sulphuric Acid.* A. H. Bucherer. Chem. Zeit. 17, 1597.

See under VII., page 249.

*Purification of Water.* Villon. Revue chim. ind. 1893, 87.

See under XVIII. B., page 271.

*The Electro-deposition of Iridium.* W. L. Dudley. J. Amer. Chem. Soc. 1893, 15, 274–276.

ACCORDING to the author's experiments made in 1884, it is not practicable to prepare baths of iridium solutions electrolytically, strictly chemical methods being necessary. It follows that the strength of the bath cannot be maintained by the dissolution of an iridium anode, and that other means must be adopted for meeting this need. Finally he found that the strength of the bath could be kept constant by surrounding each anode (a carbon plate) with a loosely-fitting linen bag containing  $\text{Ir}(\text{OH})_3$ , the acid liberated at the anode being thus immediately neutralised. The salts suitable for use as electrolytes are sodium iridochloride, ammonium iridochloride, and the double sulphate of iridium and ammonium. Iridium, like all hard and brittle metals, tends to form blisters in depositing, and needs care in the adjustment of the current density.

The method described above was discovered independently by W. H. Wahl in 1890.—B. B.

## PATENTS.

*Improvements in Electrolytic Cells and Diaphragms.* J. Hargreaves, Farnworth-in-Widnes, and T. Bird, Cressington. Eng. Pat. 18,039, October 10, 1892.

A DIAPHRAGM or cell is formed by depositing a pulp of asbestos, vegetable or other suitable fibre, upon the inside (apparently) of a vessel or diaphragm of the required shape and made of wire gauze or perforated sheet metal. Upon

this is deposited a second stone-like layer of such material as Portland cement, or a mixture of clay and sodium silicate. The metal of the diaphragm forms the cathode, the part of the diaphragm in contact with it being rendered specially porous as above to facilitate the liberation of the hydrogen; this specially porous layer may, however, be dispensed with in certain cases.—E. T.

*Improvements in the Manufacture of Alkali and in Apparatus therefor.* J. Haigreaves, Farnworth-in-Widnes, and T. Bird, Liverpool. Eng. Pat. 18,871, October 21, 1892.

See under VII., page 250.

*Improvements in Means or Apparatus for Use in the Application of Electricity for Heating Liquids, and in Means or Apparatus for Manufacturing the Same.* R. E. B. Crompton and H. J. Dowsing, London. Eng. Pat. 258, January 5, 1893.

TUBES of copper or other material with a suitable coefficient of expansion by heat, are covered with a coating of enamel of high melting point, and mounted in a lathe in such a manner as to allow of their being heated while rotating. The wire, for which copper or a copper alloy is not suitable, is then wound on, whilst the enamel is in a viscous state, and is covered with a second coat of enamel, the process being finally completed in a furnace.

For use in geysers, &c., these tubes may be filled with sand, and bent while hot into spiral or other convenient form. A former patent, No. 17,091 of 1892, contains details as to enamel to be used, and the method of heating it.—E. T.

*An Improved Method of Manufacture of Elements or Plates for Secondary Batteries.* H. F. K. Picard and H. Thame, London. Eng. Pat. 600, January 11, 1893.

SUFFICIENT lead is poured into a hot metallic mould, "lubricated" with graphite or such material, to form a "pole rim" to which the external electrical connections are to be made. The mould is then filled up with a sub-sulphide of lead, formed by pouring molten lead slowly from a height into melted galena. On cooling, the plate is in a finely-crystalline, homogeneous state, and in metallically good connection with the "pole rim." It is intended, by the elimination of the sulphur during the after-forming process, to leave the plate in a very porous state, while the inventors claim that it is still mechanically strong.—E. T.

*Improvements in the Method of and Apparatus for the Electrolytical Separation of the Bases of Salts and of Compounds of the Same from Saline Solutions.* C. T. J. Vantin, London. Eng. Pat. 2267, February 1, 1893.

THIS invention relates to the separation by electrolysis of the bases of salts, and compounds of the same, from saline solutions, in which the base of the salt electrolysed is to be obtained as metal or amalgam, or a solution of any desired salt, a diaphragm of the usual form being dispensed with by a liquid mercury cathode supported by a reticulated mesh or sieve or perforated plate of non-conducting or insulated conducting material. Apparatus is shown and described, in which the mercury is held in a supporting frame for vertical, horizontal, and oblique or slanting use; in the last case the sieve, perforated plate, &c., being provided with upright divisions to support mercury thereon in a series of steps or terraces. Methods for making liquid-tight joints around the walls of the mercury compartments are described, to separate the electrolytic face of mercury from the back or opposite face, which may be in contact with solution different from the electrolyte, as oil or water, the former to obtain amalgams, and the latter solutions as sodium hydrate from sodium salts. The inventor says that mercury will not pass through the apertures of a reticulated mesh or sieve or a finely perforated sheet up to a coarseness of about 60 meshes to the inch, or equivalent fineness of perforations, without considerable shock or pressure, but will support a small layer or head having an active surface of

about 60 per cent. of the whole area of the sieve or mercury layer. In the horizontal forms of arrangement the escape of hydrogen or other gas freed upon the active surface of the mercury must be arranged for.—J. C. R.

*Improvements in the Manufacture and Production of Elements for Secondary Batteries.* The Lithanode and General Electric Company, Limited, and J. T. Nihlett, London. Eng. Pat. 4691, March 3, 1893.

TO render lithanode plates more porous and so allow of greater discharge rates, an inert or comparatively inert material is added to the ingredients of the plates—litharge and ammonium sulphate, usually. This material, magnesium sulphate or other suitable salt, is afterwards dissolved out, leaving the plate more porous.—E. T.

*Improvements in the Utilisation of Chlorides of Sodium and Potassium for the Obtainment of Useful Products.* T. Parker and A. E. Robinson, Wolverhampton. Eng. Pat. 4920, March 7, 1893.

See under VII., page 250.

*An Improved Process of Manufacturing Bleaching Solutions by Electrolysis.* A. J. Boulton, London. From O. Knoefer and F. Gebauer, Charlottenburg, Germany. Eng. Pat. 5578, March 17, 1893.

See under VII., page 250.

*Improvements in Storage Batteries.* W. P. Thompson, Liverpool and Manchester. From M. Hartung, Berlin, Germany. Eng. Pat. 5844, March 18, 1893.

A GRID is constructed of intersecting bars of triangular section. In one set of parallel bars the base of the triangle is turned towards one side of the plate; in the other set of bars the base of the triangle is turned towards the other side of the plate. The pellet of active material is thus locked in position.

The mode of construction of the grids is not described.  
—E. T.

*Improvements in Materials for Diaphragms for Use in Electrolytic Processes, applicable also for Filtering and other Purposes.* E. T. Parker, Wolverhampton. Eng. Pat. 6605, March 29, 1893.

DIAPHRAGMS, according to this inventor, hitherto used in electrolytic processes, are subject to rapid disintegration, or great variation of electric resistance, and his object is to obviate these objections by the use of fluoride of calcium, or fluoride of aluminium, or "eryolite," in or as diaphragms for use in electrolytic processes, or for filtering or other purposes in chemical operations, where glass and the silicates would be attacked and acted upon; the fluorides being made into the form of wool, after the manner of slag wool, or woven or otherwise incorporated or made into a coherent article used as cloth, or as a lining for perforated vessels.—J. C. R.

*Improvements in Secondary Electric Batteries.* W. Petschel, Berlin, Germany. Eng. Pat. 19,567, October 23, 1893.

IN A U-frame of lead or suitable material is packed a series of strips of thin lead tape. By corrugations or any suitable means these strips can have slight spaces between them in which the liquid can circulate, and which allow of more perfect formation.—E. T.

*Improvements in Disinfecting, and Apparatus for that Purpose.* E. Hermite, C. F. Cooper, and E. J. Patterson, all of London. Eng. Pat. 22,279, November 21, 1893.

See under XVIII. C., page 271.

*New Improved Electro-positive Galvanic Battery Electrodes.* C. A. J. H. Schroeder and H. E. R. Schroeder, London. Eng. Pat. 22,956, November 29, 1893.

INSTEAD of ordinary zinc electrodes are used containing also lead and aluminium in varying proportions, the zinc, however, being always in relatively large, and the aluminium in relatively small proportion. Plates as hard and dense as possible are rolled out, amalgamated, and pressed together to form compound plates.

Others are described containing, in addition to the above ingredients, "any suitable bariun compound," manganese, iron, and mercury. The material is always to be subjected to great pressure to make it very dense and reduce local action.—E. T.

*Improvements in Apparatus for Electrolytically Producing Soda and Chlorine.* H. Lake and Co., London. From the Union Chemical Company, New York, U.S.A. Eng. Pat. 23,436, December 5, 1893.

APPARATUS is described and shown in this invention for decomposing solutions of chloride of sodium for obtaining chlorine as gas, and soda as solution. The containing vessel, of iron, acts as a cathode, and collects the soda; the anode is of gas-retort carbon, to which electrical connection is made by carbon pins driven into holes drilled in the ends of the carbon, and, to avoid corrosion, the carbon pins are impregnated with paraffin under pressure, or the terminal ends may be protected by an envelope or coating of glass or other insulating substance. The anode stands upon an insulated base resting on ganze at the bottom of the tank, with the pieces of carbon vertical, connection to the outside being made by wires, attached to the carbon pins, carried through an insulated pipe; and above them, dipping below the level of the solution, is a dome or bell of stoneware to collect the chlorine gas, which may be connected with an exhauster, and by which fresh brine is introduced.—J. C. R.

*Improved Process and Apparatus for Dissociating Soluble Salts by Electrolysis.* H. Haddon and Co., London. From H. S. Blackmore, Mount Vernon, N.Y., U.S.A. Eng. Pat. 23,913, December 12, 1893.

THE apparatus described in this invention has three chambers or tanks, two containing water, and another, between them, having a lower level and less depth of electrolyte, a solution of sodium chloride, separated from the water chambers, into which the electrodes dip, by porous, or "dialytic" diaphragms, to oppose the passage of any portion of the electrolyte through the diaphragms into the (water) tanks, which is effected by their higher level. It may be understood that the electrodes dip into weaker solutions of electrolyte than that contained in the middle compartment, which would feed them, water only being mentioned as run into these compartments.—J. C. R.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

*Mineral Oils on Ships in the Tropics.* C. A. Lobry de Bruyn. Chem. Zeit. 17, 1412.

STEAMSHIP engineers find it necessary to use vegetable or animal oils in place of mineral oils as lubricators in the tropics. At the suggestion of the author, American cylinder oil, a thick mineral oil, has been tried as a lubricator on a number of steamships. The best kinds of

this oil have the consistency of vaseline, and, in fact, according to their constitution, are nothing but unbleached vaseline.

Extensive experiments extending over almost a year, on about 20 men of war in the Dutch East Indies, have proved that a mixture of this cylinder oil with mineral oils forms a splendid lubricator. These mixed oils have a great advantage to the engineer. By varying the proportions for mixing, he can get an oil of any viscosity he may require to suit the different machinery. These mixtures are much cheaper than fatty oils, even when the latter are mixed with mineral oils.—H. M.

*Composition of Rape-Seed Oil.* G. Ponzio. J. prakt. Chem. 48, 187—188.

REIMER and Will (this Journal 1887, 218 and 732) stated that rape-seed oil contains, besides erucic and rapinic acids, a small quantity of behenic acid (melting point 75° C.). The author, by using their method of extraction, obtained from 1 kilo. of rape-seed oil 0.4 gram. of an acid melting at 75° C. He recommends, however, the following process:—1 kilo. of the oil is saponified on the water-bath with 150 grms. of caustic potash in 300 grms. of alcohol, water is added, and the acids precipitated by sulphuric acid. The mixed acids are then dissolved in alcohol and treated with an alcoholic solution of 50 grms. of zinc acetate added in small portions at a time, with constant stirring. A precipitate of zinc salts is formed, which is suspended in water and decomposed with dilute hydrochloric acid on the water-bath. The liberated acids are dissolved in a little warm alcohol, the solution being then cooled in ice. An acid separates which, on being twice recrystallised from alcohol, melts at 75° C. It is arachic, and not behenic acid, as was proved by the melting point and ultimate analysis, as well as by the properties of its amide and esters. It constitutes about 1 per cent. of the acids in the oil.—J. W.

*Cotton Stearin and Maize Oil.* F. Hart. Chem. Zeit. 17, 1522.

THE author has redetermined the physical and chemical constants of these two fats. The results are given in the following tables; those obtained for maize oil are contrasted with Spuller's numbers.

### COTTON STEARIN.

Colour.....	Pale yellow.
Consistency.....	Butter-like.
Specific gravity at 19° C. ....	0.947.
Melting point.....	30° 31° C.
Melting point of the solid fatty acids.....	45.5°—47.5° C.
Free fatty acids.....	Absent.
Helmer value.....	96.3.
Saponification value.....	194.6.
Iodine absorption.....	93.6.
Unsaponifiable matter.....	0.50 per cent.
Thermal reaction with concentrated $\text{SO}_3\text{H}_2$ .....	18° C.
Colour reaction with concentrated $\text{SO}_3\text{H}_2$ .....	Dark purple red.
Colour reaction with Beechi's reagent.....	Dark black.
Colour reaction with Wellmann's reagent.....	Dark green, on addition of ammonia base.

Addition of colza oil, however, prevents the reaction with Beechi's reagent.

## MAIZE OIL.

	Spaller.	Hart.
Colour .....	..	Dark brown.
Consistency .....	..	Liquid.
Specific gravity at 15° C. ....	..	0.9283.
Melting point of solid fatty acids. ....	..	25° C.
Free fatty acids in terms of oleic acid. ....	Absent	0.75 per cent.
Holmer value. ....	94.7	95.7.
Saponifiable value of the oil. ....	188.1	189.2
"    "    "    fatty acids. ....	..	198.4.
Iodine absorption of the fat ..	119.4	119.9
"    "    "    fatty acids. ....	..	125.0.
Unsat. saponifiable matter. ....	1.55 per cent.	1.55 per cent.
Thermal reaction with concentrated $\text{SO}_3\text{H}_2$ . ....	56° C.	60.5° C.
Colour reaction with Bechler's reagent. ....	..	But little blackened.
Colour reaction with Wedmann's reagent. ....	..	Dark green, on addition of ammonia blue.
Colour reaction with concentrated $\text{SO}_3\text{H}_2$ . ....	..	Beautiful dark red.

The unsaponifiable matter in maize oil consists to the greatest part of phytosterol, as evidenced by the melting point and the colour reaction with concentrated sulphuric acid and chloroform.—J. L.

*Effect of Electrical Treatment in Improving the Quality of Oils.* L. A. Levat. Comptes. rend. 1893, 117, 734.

OLIVE oil of inferior quality, of high colour, and acid taste was placed over water at the negative electrode of a voltmeter, which was set in action by a small Siemens machine. The oil became improved in colour, almost sweet in taste, and possessed a pleasant, very agreeable odour. In the case of lubricating oils, containing as much as 5 per cent. of free acid, the acidity was very much diminished.—A. K. M.

*Kapok Oil.* R. Henriques. Chem. Zeit. 17, 1283.

Kapok oil is a vegetable fat expressed from the seeds of *Erisodendron anfractuosum* (or *Bombax pentandrum*), a plant belonging to the *Malvaceae*, and related to the cotton plant (this Journal, 1893, 923). The seeds of the Kapok tree also resemble, in many respects, cotton seeds. The oil recovered from them is brought into the European market by the Dutch and is used in soap making; in its home (East India, West Indies) the oil is also employed for culinary purposes.

A sample of this fat supplied by a Dutch firm furnished, on examination, the following physical and chemical characteristics and constants.

PHYSICAL AND CHEMICAL CHARACTERISTICS AND CONSTANTS.

Colour .....	Greenish-yellow.
Taste and odour .....	Not unpleasant.
Consistency .....	Viscous.
Transparency .....	On keeping, becoming clear with separation of stearin.
Thermal reaction with concentrated $\text{SO}_3\text{H}_2$ . ....	95° (higher than for cotton-seed oil).
Colour reaction with concentrated nitric acid. ....	Similar to that obtained with cotton-seed oil, but appearing more slowly and more greenish.
Specific gravity at 15° C. ....	0.9199.
"    "    "    of fatty acids ..	0.9162.

PHYSICAL AND CHEMICAL CHARACTERISTICS AND CONSTANTS—continued.

Melting point of fatty acids. ....	29° C.
Solidifying point of fatty acids ..	23—24°.
Saponification value of oil .....	181.
"    "    "    fatty acids. ....	191.
Mean molecular weight of fatty acids. ....	293.
Iodine value of oil .....	116.
"    "    "    fatty acids. ....	108.
Holmer value .....	94.9.

—J. L.

*The Oxygen Absorption, Acid and Iodine Numbers of Various Drying Oils.* L. Lettenmayer. Chem. Zeit. 17, 1506.

As drying oils may be counted linseed, lallémantia, hemp seed, nut, poppy seed, sunflower, and madia oil. These all contain varying amounts of oleic, linoleic, linolenic, and isolinolenic acids, which being all unsaturated compounds readily absorb oxygen or iodine, so that their power of taking up the latter becomes a test of their value to painters. Oxygen absorption, however, only takes place when they are spread out in thin layers; in bulk they become rancid, acids of lower carbon-content being formed together with carbonic anhydride and glycerin; and this rancidity also occurs when pigments have been mixed up with them. Experiments were carried out on the drying power of thin films of the following oils which were all from the first pressing of the several seeds:—(1) East Indian and (2) Baltic linseed, (3) crude and (4) bleached nut, (5) poppy seed and (6) hemp seed oils. During the first few days of exposure all except (4) lost in weight, the loss being greatest in the case of (3), less in the others in the following order: (6), (5), (1 and 2). The linseed oils were some time before they began to gain in weight, but finally the absorption was very rapid, and they yielded films covered with reticulations, while those from (5) and (3 and 1) were smooth. For this reason poppy and nut oils are the best for oil painters. (4) gained 0.3 per cent. in weight in one day and 0.4 per cent. in a week, while the others gained 0.9 per cent. in 10—11 days, and the increase continued in the case of (3 and 4), (6), and (5) for 50 days, and after 150 they began to lose again. Lallémantia (*lallémantia ibérica*) is the quickest drying oil of all, then in order come (1), (3), (5), (6), and (1 and 2).

Freshly pressed oils give the highest iodine numbers, and if they are kept in closed vessels filled up to the neck, these do not decrease, age having no influence, but if exposed to the air, the iodine absorptions become lower. Linseed oils vary considerably in their power of absorbing iodine, while the others have a nearly constant value. The acid numbers are liable to considerable alteration when the oils are exposed or when the vessels are frequently opened, but the bleaching process carried out with hydrogen peroxide has no noticeable action on them. Painters should always employ oils of the first pressing, and for this reason it is advisable that artists' colourmen should prepare them themselves.—F. H. L.

*The Analysis of Lubricating Oils containing Blown Rape Oil and Blown Cotton-Seed Oil.* T. B. Stillman. J. Amer. Chem. Soc. 1893, 15, 265.

See under XXIII., page 286.

*Soaps most Useful for Scouring Woollen Goods.* J. Lewkowitsch. J. Soc. Dyers and Colorists, 1894, 42—53.

THE author reviews in the introduction the natural fats used in the production of textile soaps and the properties of the soaps obtained from each individual fat. He considered tallow, palm oil, cotton-seed oil, linseed oil, olive oil, cocoa-nut oil, and palm-nut oil.

*Tallow* requires weak leys for saponification and little salt to throw it out. It yields a white hard soap; too hard, in fact, to be used by itself, inasmuch as it would damage the fibre in scouring or washing. Therefore, tallow is only used admixed with other fats.

*Palm oil soap* is similar to tallow in many respects; it differs, however, in that it is easily saponifiable owing to the large amount of free fatty acids it usually contains. Like tallow, palm oil is mostly used in admixture with other fats.

*Cotton-seed oil* requires very weak leys for saponification and is difficult to salt out. The soap made from it is soft, and has the disagreeable property of possessing a very unpleasant smell, owing, no doubt, to the fact that cotton-seed oil is a semi-drying oil, the fatty acids of which undergo some oxidation process. Besides, colouring matters and resinifying bodies contained in the oil, produce yellow stains in the finished soap. Cotton-seed oil is preferably used for making soft soaps.

*Linsed oil* finds its application in the production of soft soaps; it is only used for inferior kinds of hard soaps.

*Olive oil* is the best possible material for textile soaps. Like tallow it requires but little salt to throw it up; the curd is, however, less hard, resembling a curd made from equal parts of tallow and lard. Owing to its chief property of remaining liquid and fluid, even in very concentrated solutions, olive oil soap is the textile soap "par excellence."

*Cocoa-nut oil*, in contradistinction from the previously mentioned fats, is not saponified easily by weak leys, requiring as it does strong leys. Saponification is so readily effected by the latter, that it suffices to stir the oil well into caustic lye and allow the mixture to stand, when the combination will take place in course of time. Cocoa-nut oil further differs from the foregoing fats in that its soap requires very large quantities of salt for separation, so large, indeed, that it would be altogether disadvantageous to prepare pure cocoa-nut oil soaps by the "salting out process." This soap becoming easily rancid, the oil is only used in admixture with other fats.

*Palm-nut oil* is in most respects similar to cocoa-nut oil. It requires strong leys for saponification and large quantities of salt to "salt it out."

The last two fats form, in conjunction with tallow, an excellent material for the best "curd" soap made for the woollen trade.

*Bone fat, kitchen fat, ship fat, and curriers' grease* are also largely used for making scouring soaps, the quality of which would largely depend, *ceteris paribus*, on the quality of the raw material employed. Thus, bone fat recovered by the benzine process would be a most undesirable ingredient for textile soaps.

A very important raw material for making soaps for the woollen trade is *oleic acid*. Being a free acid it is easily saponifiable and being a stronger acid than carbonic acid, it can be made into soap by simply boiling it up with sodium carbonate. It is a most suitable material for textile soaps and is largely used for that purpose. The "olefine" soaps, as they are called, if prepared carefully will give the same effect as an olive oil soap.

Of the soap stock substitutes, the author condemns "recovered grease" altogether, although it is largely used. The "crude grease" from which the material is distilled is, to begin with, after contaminated with mineral oils, which pass over into the distillate, along with some other hydrocarbons formed by destructive distillation and with certain quantities of unsaponifiable matter (this *Journal*, 1892, 142). The author further deprecates the employment of resin for textile soaps, the resinate being liable to give lime resinate in the milling process, which is very difficult to remove in the ordinary way, thus causing endless trouble in the subsequent dyeing operation.

*Filling materials* should be altogether absent from soaps for the trade. *Sodium silicate*, although extensively used for lower class scouring soaps, will tend to weaken the fibre, perhaps even destroy it by acting mechanically, thus breaking the tender fibres of the wool. For in the washing operation the salt will be precipitated within, and

on the fibre as calcium silicate and silicic acid. All other filling materials are absolutely condemned by the author.

As to the action of soap, its general application for washing and scouring purposes is undoubtedly due to its property of easily penetrating within the fibre, and coming into intimate contact with the fibre, of easily removing the fat by emulsifying it and consequently giving the water a chance of washing it off the fibre. The old view, due to Chevreul, that soap was decomposed by cold water into free caustic alkali and an acid salt, which latter is deposited on the fibre, preventing the dirt from settling down again on it, attributed the scouring, washing, and emulsifying property of soap to the dilute solution of the caustic alkali. This view, however, was an erroneous one, since a very dilute solution of caustic alkali could not replace soap, and for the further reason that a hot and clear soap solution (when no hydrolytic action has taken place to all appearances) cleanses far better than a cold one.

A better explanation, based upon experiment, had been suggested by *Rotundi*, who had shown that soap is split up into two salts, viz., a basic salt, which remained in solution, and into an acid salt, which settled down on cooling. The alkaline salt, at a higher temperature, being able to dissolve the acid salt, a clear solution is obtained directly by dissolving soap in warm water. The detergent property of soap may still be considered as due to the alkaline salt only, whereas the acid salt may simply fulfil the function of depositing itself on to the fibre and preventing the dirt from settling down again on it.

Passing on to the employment of soap in the woollen trade the author considered the three stages at which it was used, viz.: firstly, for scouring the raw wool; secondly, for the scouring of the woven fabric; and thirdly, in the milling and fulling process, the two last operations being considered together as being so nearly related to one another, that the two expressions were used promiscuously, although certainly the machines used for milling and fulling were different.

In answer to the question as to what soap should be used at any of these three stages was: any soap that is neutral, free from alkali, not containing any unsaponified fat, free from resin, mineral oil and other unsaponifiable substances, and lastly, devoid of silica and other filling material.

A soap fulfilling all these conditions was a well-made olive oil soap, the excellent qualities of which were well recognised by the trade. The only objection to its extensive use, if objection it was, was its high price.

In the *scouring of the raw wool* any soap, containing free caustic alkali would act most injuriously on the wool, destroying its surface by pitting the scales and taking away the lustre. This deleterious action of free alkali would rapidly increase with a rise in the temperature of the wash water. Although for lower classes of wool soaps containing sodium carbonate or even a dilute solution of sodium carbonate might be permissible, still, for the very finest wool a neutral soap, preferably a neutral potash soap, should be used. The highly praised "secret powders" were nothing better than frauds, and should, therefore, be guarded against carefully.

The object of *scouring the woven fabric* being to remove the lubricant employed in spinning the wool, the quality of soap would naturally depend on the quality of the goods as having previously determined the quality of the lubricant.

For the finest and best goods, which were spun with olive oil or best "olefine," a neutral soap would be required. For worsteds, which were, as a rule, not milled, potash soaps should be used.

The reason why preference is and should be given to potash soap is found by the author in the fluidity and easy solubility of potash soap, which enabled it to easily penetrate within the fibre, and consequently to do its work quickly, whereupon it could be washed out just as quickly. This explanation was illustrated and supported by the demonstration of several solutions of hard and soft soaps made from exactly the same stock of fat with varying

quantities of water. The solution of soft soap,—1:7.5—was shown to possess far greater fluidity than the solution of hard soap—1:100.

For lower qualities of goods, alkaline soaps were permissible, and, in the opinion of practical men, even necessary. For the lowest qualities of mixed mungo and cotton goods the lowest qualities of soaps were in vogue, their "strong action" being considered indispensable. The author was of opinion that good soaps would be preferable, as the scourer could add himself any alkali he considered necessary.

Granting that an alkaline soap may be required, the author tried to explain its action in the following way:—For lower classes of goods inferior lubricating oils, easily oxidised and readily resinifying, were generally used, and a strong action was required to remove them. It had to be assumed, according to Rotondi's experiments, that soap in solution was decomposed into an acid and alkaline salt. By using free alkali along with the soap, the acid salt, which would be practically useless as a scouring agent, was rendered alkaline again, and converted into a neutral or even alkaline soap. If a neutral soap resulted, it would be split up like a neutral soap, but if it had been converted into an alkaline soap it would act just in the same way as the alkaline salt got from soap. The acid salt would consequently dissolve easily, and what is more important, it would be washed out easily, carrying with it the emulsified lubricant.

In the scouring of *dyed* goods a neutral soap should be used, as the colour might be destroyed or bleed out.

In the *milling* operation the cloth underwent felting and shrinking, and in the opinion of some writers a slightly alkaline reaction of the soap tended to raise the scales of the woollen fibres, thus allowing them to slip more easily into one another, and producing more quickly the desired effect. In the author's opinion, however, soap required for milling the woven fabric should be a good neutral soap, free from any excess of alkali, and free from any unsaponified fat or unsaponifiable matter.

In support of his views was cited the fact that for the finest goods as a rule an absolutely neutral soap was used, some manufacturers even adding ammonium carbonate to the cloth in the stocks so as to neutralise any free alkali.

By means of several analyses of good household soaps and by reference to the quality of the best toilet soaps, the author showed that neutral soaps can be supplied to the trade, if the proper price was paid. He exhibited further several "milling" and "scouring" soaps, and discussed their value as indicated by analysis. A ready qualitative test for alkalinity of soaps was shown in the application of phenolphthalein solution to a freshly cut surface of the soap.

The author strongly advised the woollen manufacturers to prepare their own soap, and pointed out as the most suitable material oleic acid. Although no experienced soap-maker would find any difficulty in making the oleine soap with either caustic alkali or carbonated alkali, the woollen manufacturer had better use the former, as in the latter case boiling over and consequently loss of material might ensue.

In conclusion the author laid stress on the necessity of removing lime from the wash-water, its presence causing waste of soap, precipitation of lime soap on the fibres, and subsequent production of stains on the cloth. Several lime soaps, prepared from completely and partially saponified fat were demonstrated, proving by their clamminess and greasiness the difficulties the removal of such substances from the fibres must entail.

In the lengthy discussion following the reading of the paper, the injurious action of silicated soaps was recognised and absence of resin considered necessary by most speakers. The difference of action of potash and soda soap was ascribed by Mr. Leach to the presence of glycerin in the former, which was said to impart to the wool the "feel" that readily distinguished potash-scoured wool from soda-scoured wool in the hands of an expert. To this opinion, however, the author took objection, as, in his opinion, the glycerin was present in a too extremely dilute solution as to exert any influence. This question, however, he suggested,

should be settled by experimenting with a neutral soda soap with addition of the corresponding quantity of glycerin. Mr. Hey condemned the use of hard soaps as requiring higher temperature and more mechanical action; he further advised the use of some water-soluble lubricant. As the author pointed out, such lubricant was used abroad in the shape of castor-oil soap or of a neutral salt of sulphoricinoleic acid. Finally, the author declared that the removal of mineral oil offered no difficulty, and pointed to some experiments of his own demonstrating that a neutral soap was far better able to emulsify mineral oil than one containing free alkali.—J. L.

#### PATENTS.

*Process for the Distillation of Substances having a High Boiling Point.* Benno Jaffé and Darmstaedter, Charlottenburg, Berlin. Eng. Pat. 1468, January 23, 1893.

See under I., page 239.

*Improved Manufacture or Production of Soap.* J. Peacock, Croydon, Surrey, and W. B. Colls, Barnes, Surrey. Eng. Pat. 5621, March 15, 1893.

The following composition is stated to be "very beneficial in improving the appearance of the skin of the user." 92 lb. of the dried shavings of curd soap, or like soap, which will allow of its being milled; 1½ oz. of boric acid, made into a saturated solution with water; and about 8 lb. of yolks of eggs are thoroughly milled or incorporated; the mixture is then made into cakes in the ordinary or any suitable way.—C. R. A. W.

*Improved Detergent Compound or Preparation for the Washing or Scouring of Textile Fabrics or other Articles.* W. Brothers, Rawtenstall, Lancashire. Eng. Pat. 6123, March 22, 1893.

Solid ammonium hydrogen carbonate,  $\text{NH}_4\text{HCO}_3$ , is powdered and dissolved in boiling water. Or the ammonium hydrogen carbonate may be previously mixed with carbonates of the fixed alkalis or with granulated or other soap, a suitable proportion being equal quantities of these materials, or 75 per cent. of the one and 25 of the other. These compounds may also be used in the bleaching or dyeing industry, or in any other industry where it is desired to neutralise excess of acid.—C. R. A. W.

*Improvements in Treating Wool Greases and Separating their Constituents.* R. Hutchison, Cowlares, N.B., 6993, April 5, 1893.

The patentee applies the term "lanichol" (abbreviation for lanicholesterine) to the material obtained by the following process, regarding it as different from "lanolin" (or "lanoline"). Impurities of albinous, gummy, or similar character are first separated by boiling nine parts of wool grease with as much resin of soda (made by boiling together rosin and twice its weight of soda crystals) as contains one part of rosin; brine is added, and the whole boiled up with steam, enough salt being present to prevent the whole of the grease from going into solution; or salt may be added during boiling. The undissolved grease boiled up repeatedly with brine to wash out impurities, and finally with water containing alkali in solution; free fatty acids and soaps dissolved in the grease are thus washed out; on standing, "lanichol" rises to the surface, whilst good soap stock is obtained on treating the soapy wash waters with salt.—C. R. A. W.

say 80 decagrams. of the cleansing agent in 20 litres of water: finally the articles are rinsed twice in cold water. Coloured stuffs must not be boiled—C. R. A. W.

See under XVIII. A., page 270.

### XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

#### (A.)—PIGMENTS, PAINTS.

*Strontium Urinate.* T. Niederländer. Chem. Zeit. 17, 1893, 1507.

This new pigment is prepared in three distinct shades, lemon yellow, dark yellow, and orange. It is very permanent, but it has little covering power, and its chief use therefore is for blending. By prolonged exposure to strong light it becomes duller with a slight greyish tendency. The pale shades are precipitated from solutions of uranium nitrate by strontium hydrate, the former being kept in excess, and while temperature and concentration are without influence on the shade, it is found better to work hot. The darker pigments are precipitated cold from a 10 per cent. uranium solution, a considerable excess of strontium hydrate solution being employed, and the whole boiled for some time. By heating the dark yellow colour to 200°–250° C., it is gradually changed into the orange. Barium compounds may be used, and form better and more permanent pigments.—F. H. L.

*Cadmium Yellow: its Preparation and Properties.* T. Niederländer. Chem. Zeit. 17, 1893, 1505. (Compare Buchner, this Journal, 1887, 665.)

CADMIUM sulphide (*Jaune brillante*) is prepared commercially in shades varying from a bright yellow to a red, but is invariably of the same chemical constitution, containing the theoretical amounts of metal and sulphur. The paler shades are precipitated from 10 per cent. solutions of the sulphate or chloride of cadmium by sulphuretted hydrogen, the alkaline sulphides yielding pigments which from their instability are useless to painters. The stream of gas must be stopped when half the cadmium has been thrown down, and the precipitating vessel must be so arranged as to bring the sulphide into contact with the sulphuretted hydrogen as little as possible. For dark yellows, the whole of the cadmium is thrown down, the liquid being kept warm, and the precipitate constantly stirred up. To prepare cadmium orange, sulphuretted hydrogen is led into a boiling 2 per cent. solution of chloride, to which 5 per cent. of hydrochloric acid (1:3) has been added, the success of the operation depending largely on the efficiency of the agitating apparatus.

The author does not believe in Buchner's theory (*loc. cit.*) that the darker shades of cadmium sulphide are due to molecular condensation, but considers that the variation is a purely physical one, the presence of the free acid in the hot liquid when preparing the orange shade, causing the precipitate to fall more slowly and consequently in coarser particles, and that it is to the finely-divided state in which the pale yellow sulphides exist, that their lack of permanency is due.

As met with in commerce, many of the cadmium pigments are very pure, but, on the other hand, the paler shades from one well-known works contain 21.5 per cent. of zinc, which gives them a greenish cast. Cadmium yellow, dry,

exposed to light bleaches quickly, but when ground in oil will keep its shade for nine months. Some lemon yellows of a beautiful colour are prepared from the hydrate, carbonate, or oxalate of cadmium by decomposition with sulphuretted hydrogen, but these contain but little sulphide and are very unstable.—F. H. L.

*The Importance of the Study of the Chemistry of Oil-painting.* T. Petruschewsky. Chem. Zeit. 17, 1505.

In a paper read before the German Society for the Advancement of Oil-painting held in Munich, the author points out that still very little is known as to the cause of the fading of pigments, and that, as the fame of a painter is largely dependent on the permanency of his pictures, this matter should be thoroughly investigated. He advises that suitable resin varnishes should be employed instead of those containing oil only, that the finished pictures should always be varnished on the back, and that the paintings should not be exposed to direct sunlight.—F. H. L.

*The Properties of Essential Oils, and their Employment in Painting Compared with that of Mineral Oils.* L. Lettenmeyer. Chem. Zeit. 17, 1506.

See under XX., page 273.

#### PATENTS.

*Improvements in the Preparation of Oxide of Zinc Pigments.* A. P. Laurie, London. Eng. Pat. 4870, March 7, 1893.

To improve the quality of paints having zinc oxide as their basis, the inventor grinds them with a mixture of oil and free fatty acid, either produced in the linseed oil by the action of superheated steam, or added thereto during the grinding. For house painting the acids should form 5 per cent. of the varnish, for artists' use about 15 per cent., and either linoleic or oleic acids may be employed.—F. H. L.

*Improvements in the Manufacture of Red Oxide Paints.* M. N. D'Andria, Strerford, Lancaster. Eng. Pat. 5349, March 13, 1893.

THE very high temperature which it is necessary to employ to remove all the sulphuric acid contained in ferrous sulphate has a very deleterious influence on the shade, and the other physical properties of the resulting pigment. To overcome this, the inventor calcines a mixture of about equal parts of ferrous and magnesium sulphates, finding that the decomposition takes place at a lower temperature, that the colour of the oxide is brighter, and that it is formed in a finer state of division. The magnesium sulphate is removed by washing, and the gases evolved during the furnacing may be led into a vitriol chamber as described Eng. Pat. 4343, 1893; this Journal, 1894, 163.—F. H. L.

#### (B.)—RESINS, VARNISHES.

*The Importance of the Study of the Chemistry of Oil-painting.* J. Petruschewsky. Chem. Zeit. 17, 1505.

See under XIII. A., page 262.

#### PATENTS.

*Improvements in Pyroxyline Compounds, Solutions, and Solvents.* L. Paget, New York, U.S.A. Eng. Pat. 22,137, November 18, 1893.

THE inventor has found that by the action of ozone he has been able considerably to increase the number of liquids practically available as solvents of nitrocellulose.

The ozone is prepared by the electrical treatment of oxygen; it must be dry, and, at a temperature not exceeding 120° F., is blown through the oil, which is kept cold. If the latter is viscid, it may preferably be sprayed into a chamber filled with the ozonised atmosphere. Oils and other liquids which are amenable to this treatment may have been previously useless for one of two reasons—first, that they were not solvents of nitrocellulose; and second, that although solvents, they had no drying power. The inventor has tried the following liquids, and found that to the first class belong:—Oil of turpentine, camphor, methyl alcohol, acetone, acetal, ethyl amyl ether, and fusel oil (to a certain extent); while oil of caraway seed gains strongly-marked drying powers. In fact liquid solvents are not necessary in all cases, as by placing the soluble gun-cotton in a chamber and blowing in vapour of camphor, ozone, and an alcohol spray, the pyroxylin is rapidly converted into a solid mass. As an example of an ozonised liquid, the inventor finds the following to be a very good metal lacquer:—Amyl aceto-acetate, 20 galls.; ozonised fusel oil, 5 galls.; wood alcohol, 5 galls.; "benzine," 15 galls.; and pyroxylin, 15 to 20 lb.—F. H. L.

*Notes on Asphaltum.* T. Niederländer. Chem. Zeit. 17, 1893, 1507.

ASPHALTUM itself being rather a treacherous material for painters to use, the author has experimented on the action of various solvents, to see whether its noxious ingredients can be removed. He finds, however, that the residues obtained after treatment with various liquids are useless for artistic purposes, as they do not possess the characteristic lustre (*lasur-tone*) which makes this material so valuable. Alcohol extracts 4·5 per cent., but the solution is useless, as it will not dry. Petroleum ether dissolves 40 per cent., and the extract has a beautiful colour, dries well, and may be used either alone or mixed with linseed oil. The ethereal and acetone extracts are valueless. The alcoholic residue, if melted with one-third of powdered amber, may be used in oil, and possesses as fine a colour as the original substance. On the whole, the author considers that the use of asphaltum should be avoided as much as possible in painting.—F. H. L.

#### XV.—MANURES, Etc.

*Comparative Value of Various Phosphatic Manures.* N. von Dehn. Bied. Centralbl. Agrikul. 1893, 590.

THE author draws the following conclusions from his results:—1. Phosphorite and Thomas slag cannot compete with superphosphate. 2. The effect of phosphorite is directly proportional to the amount of phosphoric acid which it contains. 3. Increased manuring with phosphorites increases the production; in the case of low grade phosphorites, however, the increase is not sufficiently great to render them preferable to high-grade phosphorites. 4. The assimilability of Thomas slag always surpasses that of 25 per cent. phosphorite, but the vegetables produced are tolerably equal, which may perhaps be ascribed to local conditions.—A. R. L.

#### XVI.—SUGAR, STARCH, GUM, Etc.

*Purification of Beetroot Juice with Hydrated Basic Ferric Chloride.* Spunt and Schachttrupp. Neue Zeits. Rubenzucker Ind. 31, 108.

By the ordinary method of defecating the juice with lime and subsequent saturation with carbonic acid or sulphurous acid, it is known that many albuminous substances coagulable at a high temperature, as well as other organic non-sugar compounds are either incompletely precipitated or partially redissolved by the excess of lime. The patentees propose to use the hydrated basic ferric chloride—

or other higher basic chloride in the following manner:—The diffusion juice as it comes from the battery of diffusers is mixed at the ordinary temperature with sufficient milk of lime until its alkalinity is 0·08 per cent., and to 60 litres of juice 0·5 litre of the hydrated basic ferric chloride added, together with a further quantity of milk of lime, corresponding with 1 per cent. (on the roots) of caustic lime. The juice is now heated to 80° C., and saturated with carbonic acid to an alkalinity of 0·1 per cent. The boiled juice is filtered, pressed, and treated a second time, at first with 0·25 litre of hydrated ferric chloride per 100 litres of juice, and then with lime (0·25 per cent. caustic lime, on the roots). It is then saturated with carbonic acid or sulphurous acid to an alkalinity of 0·05 per cent., and further treated in the usual manner. Laboratory tests proved that an increase in the purity quotient of 75 to 82 was attained with crude juices, and of 85 to 90 with thin juices. The juice thus purified was free from iron. The patentees intend to extend their process to the purification of molasses.—A. R. L.

*Defecation of Beetroot Juice with Ammonia.* F. Hanuš. Zeits. Zuckerind. Bohm. 1894, 18, 161—166.

THE author's experiments relate to the defecation of the diffusion juice with ammonia, prior to saturation. Ammonia, although a more expensive material than lime, has several advantages over the latter, thus:—Certain organic non-sugar constituents, which comprise cell membrane besides other substances present in the cell contents, are not dissolved; the precipitate which results by the use of ammonia is of a crystalline nature and quickly subsides, so that the liquid can be decanted from it. The last-mentioned precipitate contains organic matters, iron alumina, lime, and much ammonium magnesium phosphate. The juice when neutralised with ammonia may be heated prior to saturation without fear of inversion taking place, and in presence of an excess of ammonia it may be kept at the ordinary temperature for several weeks without undergoing alteration. About 50 cc. of ammonia (ordinary strength) was stirred into 19 litres of diffusion juice. The author directs attention to the fact that the ammonia evolved during the saturation and evaporation of the juice is at present lost, and he suggests its possible application in this process.

—A. R. L.

*Use of Asbestos for the Filtration of Sugar Juices and Syrups.* P. A. Maignen. Bull. de l'Assoc. des chim. 10, 881.

The author recommends asbestos, either in the form of cloth or powder, as a mechanical filtering medium. Its advantages are—(1) that complete clarification is attained; and (2) that sediments of lime, &c., can be removed by treating the asbestos with hydrochloric acid.—A. R. L.

*Augmentation of the Fermentable Capacity of Molasses.* F. Greger. Sac. Indigène, 1893, 42, 651.

See under XVII., page 268.

*Action of Bases on Glucoses.* L. Jessen. Oesterr. Ungar. Zeit., Zuck. Ind. und Landwirths. 661. Neue Zeit. Rübenzuck. Ind. 31, 177, 179: 185—188.

In a previous paper (Neue Zeit. 21, 3) the author showed that the acids produced by boiling invert sugar with lime or caustic potash had an acidity (neutralising power) corresponding with "1.5 mols. of alkali or lime" "calculated on two molecules of the glucose." [Equivalents, not molecules, are possibly here meant.] He now finds that caustic baryta behaves in a precisely analogous manner. A study of the action of alkaline carbonates on dextrose, levulose, and invert sugar has in the main confirmed Herzfeld's observations (Zeit. Ver. Rübenzuck. Ind. 1890, 263), and the evolution of carbonic acid gas which the last-named chemist has observed is to be ascribed to the acids resulting from the glucoses. When 0.5 grm. of either dextrose, levulose, or invert sugar is boiled with 1 grm. of pure lime (free from carbonate) and 100 grms. of water, the amounts of carbonic acid formed are found to be respectively equal to 0.0016 grm. = 0.32 per cent.; 0.016 grm. = 3.2 per cent.; and 0.0078 grm. = 1.56 per cent.

The remaining portion of the paper deals with the behaviour of the decomposition products of invert sugar by alkalis on titration, in presence of various indicators.

—A. R. L.

*Phoma Beta, the Beetroot-destroying Organism.* Hollrung. Neue Zeits. Rübenz. Ind. 1893, 31, 165.

At the meeting of the "Zweigvereines für Rübenzucker Industrie" at Halle, the author communicated the following:—Frank has pronounced the disease produced by this organism a new one, which is not the case, for the organism was first described in 1846; Kühn studied it in 1852. The evil occasioned by the organism in France during 1851 is computed at 400,000 ctrs. of sugar. The disease is generally known as the *core-rot*, since it is characterised by the rotting, blackening, and withering of the inner rudimentary buds. The organism makes its appearance in the formation of small cavities in the buds, which in time open,

and spores result which then develop. The causes are at present unknown. Frank states that manuring with lime promotes the growth of the organism; this is, however, not so, as it has been observed in beetroot plantations which were not manured with lime. The author believes the cause of the appearance of this organism to be the stoppage in growth of the beetroots; thus he observed a stoppage in growth during the drought, which favoured the development of the disease; the organism was never found in moist localities.—A. R. L.

*Estimation of the Quantity of Juice contained in Beet-roots.* A. Vivien. Bull. de l'Assoc. des Chim. 10, 833.

The above estimation is made by the following three processes:—1. The direct estimation of the sugar in the roots, and of the same in the juice. 2. The estimation of the water in the roots and in the juice. 3. The extraction of a known weight of roots and the determination of the weight of in-soluble substances. The third method is the most accurate:—100 grms. of raspings are extracted with water at first at a low temperature, and afterwards with the same solvent at 80° C.; the extracts are decanted on to a tared filter, and the weight of insoluble substance directly ascertained.—A. R. L.

*Reports on Modified Starches prepared by Siemens and Halske, Berlin.* Bull. Soc. Ind. Mulhouse, October—November 1893, 363.

M. SCHAEFFER reports that these modified starches are prepared principally by the instrumentality of ozone generated by electricity acting on the ordinary potato-starch (fecula) of commerce. The brands named "Soluble Starch" and "Refined Starch" are perfectly white and have a greater thickening power than potato-starch of the best quality. Thickenings made with them undergo no change after keeping five days, whilst those of ordinary starch become thin after lying 24 hours. They would probably prove of value in the finishing of calicoes.

M. Schenrer reports that of the various brands the "Raw Gum," "Universal Gum No. 1," and "Universal Gum No. 2" are the ones most likely to be useful in printing and finishing, being almost entirely soluble in boiling water, whilst the Universal Gums dissolve even in cold water. They have less colour than roasted wheat-starch and locoeome (British gums), which they to some extent resemble.

Used for thickening colours, 3 to 4 lb. per gallon is sufficient. The Universal Gums Nos. 1 and 2 do not stiffen the cloth even with acetate of chrome mordants, and the shades got are as deep as and clearer than with roasted starch. The "Raw Gum" gives colours as clear as the preceding, but deeper in tone, and it stiffens the cloth a little.

The following table shows the physical and chemical properties of the six samples examined:—

Brand.	Appearance.	Coloration with Iodine.	Action on Fehling Solution.	Action of Cold Water.	Action of Boiling Water.	Appearance of Solution at once.	Appearance of Solution after 24 Hours.	Appearance of Solution after 96 Hours.	Colour of Solution.	Remarks.
Raw starch	Like inferior potato-starch, greyish.	Pure blue	None	Insoluble	Very thick and starchy with 20 per cent.	Greyish, dirty, and slightly viscous.	Loses some of its thickness.	Loses some of its thickness.	..	This is the raw material of all the brands.
Refined starch.	Like very fine potato-starch.	Pure blue	None	Insoluble	Very thick and starchy, viscous (if hot).	Very white, very viscous.	Without change.	Without change.	..	Slight smell of hypochlorite.
Soluble starch.	Like ordinary potato-starch, slightly amber-tinted.	Pure blue	None	Insoluble	Thick and starchy, less viscous.	Consistency resembling that of wheat-starch.	Thickens somewhat.	Without change.	Very slightly amber-coloured, almost white.	..

Brand.	Appearance.	Coloration with Iodine.	Action on Fehling's Solution.	Action of Cold Water.	Action of Boiling Water.	Appearance of Solution at once.	Appearance of Solution after 24 Hours.	Appearance of Solution after 36 Hours.	Odor of Solution.	Remarks.
Raw gum	Like British gum, very clear.	Blue, with a touch of violet.	Very strongly reducing.	Turbid solution with 2 per cent. substance.	Dissolves completely with 20 per cent. substance.	Gummy and transparent with 20 per cent. substance.	Slight insoluble deposit.	Deposit increased.	As above.	Does not ferment on addition of yeast.
Universal Gum No. 1.	Like gummiine, transparent and yellowish.	Violet	Strongly reducing.	Solution almost complete.	As above	Gummy and thin with 20 per cent. substance.	Slight deposit.	Hardly changed.	Like egg-white solution.	Contains a trace of chloride of calcium. Does not ferment.
Universal Gum No. 2.	As the last	Violet	As above	Solution less complete than the above.	Solution somewhat less transparent than the above.	Like the above.	Slight greyish deposit.	Hardly changed.	As above.	As above.

—W. E. K.

## PATENTS.

*Improvements relating to the Manufacture of Soluble Starch.* H. H. Lake, London. From W. Angele, Berlin, Germany. Eng. Pat. 5617, March 15, 1893.

SOLUBLE starch has heretofore been made by Lintner's method, which consists in subjecting it to the action of 7·5 per cent. hydrochloric acid at the ordinary temperature for several days, or to that of 15 per cent. sulphuric acid at a moderate temperature. The process which the patentee claims is exemplified as follows:—Dry starch is intimately mixed with sufficient dilute hydrochloric acid so that the mixture contains about 0·5—1 part of anhydrous acid to 100 parts of dry starch. This quantity of acid is diluted with as much water as is required to make a stiff paste of such consistency that it may be stirred. For example, 1,000 kilos. of dry starch are mixed with 1,000 litres of water, to which mixture 20—40 kilos. of 25 per cent. hydrochloric acid is added. The mixture is placed in a drying room on hurdles, where it is allowed to dry at a temperature of about 20°—40° C. The drying is continued until a sample completely dissolves, without gelatinisation, in hot water; the time required for this is generally about 18 hours. The required time depends in a certain degree on the perfection of the drying plant, and may be considerably reduced by first extracting a portion of the water by the aid of a centrifugal machine. In the latter case, however, the mixture must originally contain 5—10 kilos. of acid for every 100 kilos. of starch, so that, after spinning, it may contain the requisite quantity (as above) of acid. The action of the centrifugal machine causes a very intimate penetration of the acid into the starch. The acid is then got rid of by washing with cold water and with dilute solutions of alkaline carbonates, after which the product is spun in a centrifugal machine and dried in the usual manner. The process may also be carried out with hydrochloric, nitric, sulphuric, phosphoric, oxalic, lactic, acetic, and other liquid or volatile acids.—A. R. L.

*Improvements in the Continuous Refining or Bleaching of Sugar, and in Machines employed for this Purpose.* L. E. A. Prangey. Eng. Pat. 7695, April 15, 1893.

THE improvements relate to machinery for carrying out the process described in another specification (see this Journal, 1893, 702). Several layers of massecuite are deposited one above another, and successively subjected to pressure. The combination of an endless apron conveyor with a massecuite reservoir containing partitions at different levels, dividing it into hoppers which debouch at different levels above the apron, or (in the case of treating sugar in powder which is more or less dry) with a series of V-shaped hollow transverse partitions at different levels within the reservoir.

Furthermore, of pressure rollers in front of the hoppers, supporting rollers below the apron and under the pressure rollers.—A. R. L.

*Improvements in the Manufacture of Sugar.* H. H. Lake. From P. H. Van der Weyde and O. Lugo, New York, U.S.A. Eng. Pat. 136, January 2, 1894.

THE invention consists in electrolysing a sugar solution contained in a shallow tank, and heated to about 200° F. by electrodes of aluminium and carbon connected in the usual way to the poles of an electric generator, preferably a constant current dynamo machine. The E.M.F. need not be more than 4—5 volts, and the quantity is proportional to the surface of the electrodes in contact with the solution. The anode is thus attacked, producing "nascent aluminium oxyhydrates," which are said to effect the defecation and decolorising of the liquor. Although the "oxyhydrates of aluminium" are insoluble in sugar solution, they combine with certain impurities in crude sugar liquor and pass into solution as soluble compounds. To completely precipitate the latter, therefore, the patentees add a soluble phosphate—preferably in the form of bone ash, bone black, or spent bone black treated with sulphuric acid.—A. R. L.

## XVII.—BREWING, WINES, SPIRITS, Etc.

*Lac-lined Casks.* Bohmischer Bierbrauer, 1894, No. 2.

A BREWER attributes disastrous results obtained in a brewery to the employment of lac-lined casks. The lac had become porous, and teemed with wild yeasts and other organisms. He strongly advises the employment of pitch rather than lac.—A. K. M.

*The Production of Saccharose (Cane Sugar) during the Germination of Barley.* L. Lindet. Comptes rend. 1893, 117, 668—670.

THE author has examined samples of barley during various stages of germination, and finds that the cane sugar gradually increases whilst the starch diminishes, and concludes that the former is produced at the expense of the latter.—A. K. M.

4. *Study of the Use of Apple U.S. for Cider-making.*  
A. D. Comptes rend. 1893, 117, 735—767.

THE author has studied the variety *Amre* of Sarville during the various phases of its development from the blossom to the decomposition of the fruit. He divides the investigation over four periods, thus:—(1) Period of forma-

tion and development, June to September; (2) Period of maturity on the tree, October to mid-November; (3) Period of ripening in store house, November to February; (4) Further period, March to July. The results of his analyses are tabulated as follows:—

	Minimum.	Maximum.	Variation.
Sap.....	746 grs. s. fruit rott n. June, end of experiments.	8221 grms. July, end of experiments.	Varies but slightly.
Diastase.....	1504 grms. June, end of experiments.	1489 grms. July, end of experiments.	The variation in the sugars is very appreciable, that of the saccharose being greatest.
Saccharose.....	10742 grms. November, during storage period.	11360 grms. during storage period.	" "
Tannin.....	0.139 grm. fruit rotten, end of experiments.	1570 grms. November.....	" "
Pectin, albumenoids, &c.....	0.141 grm. November.....	1560 grms. July, end of experiments.	This ill-defined principle is very variable.
Pectin, albumenoids, &c.....	0.139 grm. August.....	2320 grms. July, end of experiments.	Very variable.
Tartronicity as malic acid.....	0.085 grm. for most months.....	0.151 grm. fruit rotten June.....	Slightly variable.
Vegetable tissue.....	5.050 grms. December.....	13.07 grms. June, end of experiments.	Rather variable.
Tadash.....	0.451 grm. January.....	1.287 grms. June, end of experiments.	Very variable.

—A. K. M.

*Influence of Carbon Dioxide on the Growth and Life of Fermentation-Organisms.* Jahresb. d. Königl. Lebranst. f. Obst- u. Weinbau, zu Gießenheim.

It is found that both *Saccharomyces ellipsoides* and *S. apiculatus* are considerably retarded in their growth by carbon dioxide, and the latter species to a greater degree than the true wine yeast (*S. ellipsoides*). The mould-fungi *Penicillium glaucum*, *Mucor racemosus*, and *Dematium pullulans*, on the other hand, are not merely retarded in their growth, but soon perish in an atmosphere of carbonic acid gas, whilst *Mycoderma*, the acetic ferment and *Torula* species can, under the same conditions, live for months, although unable to bud.

By means of a rapid fermentation, therefore, wine can be protected from the action of the moulds and *S. apiculatus*, but in order to protect it from *Mycoderma*, *Bacterium aceti*, and *Torula* it is necessary that as much as possible of its carbonic acid be retained in the wine during the whole period of its storage. It is not, however, advisable to employ artificial carbon dioxide to increase the stability of wine, as the latter then acquires a peculiar taste, and, on coming into contact with the air, also an objectionable brown colour.

—A. K. M.

*The Action of Calcium Sulphite and of Potassium Bisulphite on Alcoholic Fermentation.* F. Ravizza. Le Staz. Sperim. Agr. ital. 24, 1893, 593.

From experiments made with artificial must, prepared by adding invert sugar solution—inverted by means of tartaric

acid—to the juice of white grapes, the author finds that small quantities of calcium sulphite are without effect on the fermentation, whilst quantities sufficiently large to produce a retarding effect, would prejudice the character of the wine. Potassium bisulphite has a more strongly retarding, and hence regulative effect.—J. G. W.

*Studies on Yeast.* II. Elien. Cent. für Bakt. und Parasit. 1893, 53; Zeits. für Spiritusind. 17, 1894, 11.

THE amount of carbon dioxide evolved when yeast acts on sugar solutions under certain conditions varies with the variety of yeast used, and may be made use of to distinguish these varieties. The author employs the determination of the amount produced of this gas to calculate out two constants for the yeast, viz., the fermentative power and the fermentative energy; the fermentative power being defined as the total amount of sugar a given amount of yeast is able to ferment, while the fermentative energy is the amount fermented by a given quantity of yeast in a given time.

The carbon dioxide was determined by the volumetric method, taking, however, the precaution to expel the gas contained in the fermented liquid at the close of the experiment, as the author finds, contrary to Hayduck, that the amount retained in solution at any time while fermentation is proceeding may vary.

The following are some of the results obtained by the author:—

Variety of Yeast.	Quantity of Yeast.	Time of Fermentation.	Sugar.	Water.	Temperature.	CO <sub>2</sub> evolved.
	Grms.	Hours.	Grms.	Ce.	° C.	Ce.
Bottom yeast I.....	2.5	2	10	100	35	328
" " I.....	2.5	2	10	100	30	330
" " II.....	5.0	2	10	100	30	660
Top yeast in pure.....	5.0	2	10	100	18	274

The presence of phosphates largely increases the fermentative energy, but different yeasts are influenced to a different extent. The fermentative energies of different varieties of yeast show still more variation when determined at varying temperatures.

The fermentative energy of a yeast is no guide to its value for baking purposes, and the author finds that, contrary to the opinion of many, the presence of bacteria is not essential to a good baking yeast. He emphasises the importance of the fact that some yeasts have a very great

fermentative energy at comparatively high temperatures, and that among these are varieties which are undesirable for brewing purposes, but which may be most suitable for the bakery (this Journal, 1888, 636).—J. G. W.

*The Influence of Certain Chemical Conditions on the Activity of Brewers' Yeast.* J. Effront. Comptes rend. 1893, 117, 559—561.

THE experiments described lead the author to the following conclusions:—1. That when yeast is cultivated in wort containing per litre, 200—300 mgrms. of ammonium fluoride, its power of reproduction is sensibly weakened, but that the different species are affected in varying degrees. 2. That a wort containing 200—300 mgrms. of fluoride per litre, can be employed for the cultivation of all beer-yeasts without distinction of race, and with the same success, if they have previously become accustomed to the presence of fluoride. 3. That yeasts which have been cultivated in the presence of gradually increasing quantities of fluoride acquire a greatly increased fermentative activity—ten times greater than before treatment—and exhibit properties which physiologists have hitherto regarded as belonging exclusively to certain races.—A. K. M.

*The Kilning of Malt in Relation to the Colour of the Malt-Germ.* Cerny. Oesterr. Brauer- und Hopfen-Zeitung, 1894, No. 1.

EXPERIMENTS conducted by the author show that the germs of an undergrown and of a normally grown malt were darker than in the case of an overgrown malt, although the conditions of kilning were identical. The colours of the worts, however, were the reverse, the malt with the long plumule giving the darker wort. Consequently, to produce equal results as regards colour, the undergrown malts require more kilning than overgrown malts. In explanation of the above results, the author further expresses the opinion that the colouring matter of malt is formed in the radicle, and on further growth becomes subsequently translocated to the plumule.—A. K. M.

*Some Products of Starch Transformation.* W. L. Hiepe. The Country Brewers' Gazette, 1893, No. 431; 1894, Nos. 433, 434, 435.

*Experiments with Isomaltose.*—Isomaltose was prepared by Lüntner's method, and its fermentability was tested with various yeasts and with the following results:—

Type of Yeast.	Percentage of Sugar Fermented.
S. Cerevisiae, Saaz (Jørgensen 255) .....	24.1
" Froberg (Jørgensen 60) .....	57.1
" High fermentation type .....	54.3
S. Pastorianus I. ....	56.3
" II. ....	47.3
" III. ....	43.1
S. Ellipsoidens I. ....	43.0
" II. ....	58.3
S. Exiguus .....	27.2
S. Apiculatus .....	None.

The exact conditions as regards time and temperature are not stated.

*Examination of Commercial Amyloins.*—The author has examined the two products known as A and B, and his results lead him to the following conclusions:—(1.) The commercial amyloins are partly fermentable by nearly all species of yeast. (2.) Diastase produces an increase of

reducing power and decrease of rotatory power, together with an increase of solids. (3.) After the action of diastase, or by diastase and yeast together, they are practically completely fermentable. (4.) The phenyl hydrazine test shows the presence of glucose, maltose, and isomaltose. (5.) The fractional precipitation gives no homogeneous precipitates between dextrin and isomaltose. (6.) They consist, therefore, of a mixture of glucose, maltose, isomaltose, and dextrin; the latter being entirely hydrated by diastase and having a distinct reducing power.

The results of analysis of amyloin A indicated the following composition:—

	Per Cent.
Dextrose .....	2.85
Maltose .....	
Isomaltose .....	
Dextrin .....	36.44
Other matters .....	2.11
	100.00

The author has conducted a large number of experiments on the fermentability of the various constituents of the "amyloins" by different species of yeast. The following results taken from an elaborate table refer to the percentage of isomaltose fermented by the different yeasts:

	Per Cent.
Sach. Cerevisiae (Jørgensen 120) .....	53.5
" " " 60 .....	49.9
" " " 84 .....	54.0
" " " 255 .....	67.0
" " " 304 .....	45.8
" " (High fermentation type) .....	51.5
" Pastorianus I. ....	57.9
" " II. ....	45.5
" " III. ....	33.9
" ellipsoidens I. ....	31.4
" " II. ....	49.2
" exiguus .....	8.7
" apiculatus .....	3.2

The figures representing the dextrin and which are given in the complete table are remarkably constant and indicate that this carbohydrate is absolutely unfermentable and that the wild yeasts possess no diastatic action.

The "amyloin A" has also been submitted to an elaborate process of fractional precipitation by alcohol and the author finds it to contain dextrose, maltose, isomaltose and dextrin, whilst no substance having the properties of a malto-dextrin could be detected.—A. K. M.

*An Apparatus for Pasteurising Beer.* E. Windeck. Petit journal du Brasseur, 1893, No. 13.

THIS apparatus consists of a cylinder capable of withstanding a pressure of ten atmospheres, and containing a coil the ends of which pass through the ends of the cylinder. The coil can be rotated at the rate of about 30 revolutions in the minute thereby bringing the beer into a moderate degree of motion. Hot water is first passed through the coil so as to raise the temperature of the beer as quickly as possible to the desired pasteurising temperature; this is followed by spring water to effect a rapid and uniform cooling and finally by cold water from the ice-machine in order to attain a really low temperature. Beer treated in this manner does not lose its carbonic acid gas and does not acquire the pasteurising taste.—A. K. M.

*The Evolution of Carbon Dioxide and Hydrogen Sulphide in Boiling Beer, Hopped and Unhopped Wort and Hops.* Ehon. Rec. des Trav. Chim. des Pays-Bas, 1893, 12, 255.

THE author has found that small quantities of carbon dioxide and hydrogen sulphide are evolved when beer and hopped or unhopped wort are boiled. The evolution of a volatile sulphur compound on boiling hops with water had been previously observed by Prior. The author has made experiments to determine the effect of these decompositions on the accuracy of determinations of the carbonic acid in

beer. He obtained beer free from carbonic acid by heating it to 39° under diminished pressure and passing a current of air through it for two hours. On subsequently boiling the beer for various lengths of time, it was found that the evolution of carbonic acid was greatest at the beginning of the boiling process, but the amount is not sufficient to seriously affect the determination of the carbonic acid in beer, if the boiling be not carried on too long.

Experiments with wort gave similar results. 200 cc. of a wort containing 11.5 per cent. extract yielded 5.3 mgrs. of carbonic acid when boiled for an hour and a half.—A. K. M.

#### *Production of Coconut- and Rice Beer.* A. Calmette. La Bère, No. 1, 1894.

THE author discusses the manufacture of beer in hot countries and treats especially of the conditions prevailing in Java, Fouquin, and Saigon. After describing the primitive methods adopted and the unsatisfactory results obtained, he points out the difficulty of obtaining worts containing a sufficient quantity of saccharine matter, the employment of barley-malt being out of the question owing to its high price. On the other hand, the employment of koji or Chinese yeast for saccharifying the rice is unsatisfactory, owing to the difficulty with which the wort is clarified and on account of the musty taste which the product acquires.

The author finds that a good beer may be obtained from coconut milk which contains 9 to 13 per cent. of fermentable sugar. He adds cane-sugar, boils for an hour and a half with hops (80 grms. to the hectolitre), filters and ferments with pale ale yeast. A beer of excellent quality is obtained, containing 3.4 per cent. alcohol and 3.1 per cent. extract.—A. K. M.

#### *Augmentation of the Fermentable Capacity of Molasses.* F. Greger. *Suer. Indigène*, 1893, 42, 651—652.

THIS process has been patented in Germany and France. Maereker and Meale have recognised that molasses which ferment with difficulty contain volatile acids which exert a toxic action on the yeast, and they proposed to boil the molasses for a certain time with an excess of sulphuric acid, in order to expel these volatile organic acids. Czeczetha has constructed an apparatus for this purpose. The patentees' experiments show, however, that it is necessary to heat the molasses with a known excess of sulphuric acid at 60°—75° C., and subsequently to filter the thus sterilised liquid. By this filtration, which is carried out with either the concentrated or diluted molasses, the substances harmful to the yeast are eliminated, and the process secures the following advantages:—A better fermentation, purer alcohol, increased yield, and a great economy in yeast. The yield of alcohol is increased when molasses, which ferment readily by the ordinary mode of procedure, are treated by this process.—A. R. L.

#### *Estimation of Succinic Acid formed in Fermentations.* A. Rau. *Archiv. f. Hygiene*, 14, 225.

See under XXIII., page 237.

#### *The Determination of Malic Acid in Wines, &c.* C. Micko. *Zeits. d. Allgemeinen österr. Apotheker.* Ver. 30, 289.

See under XXIII., page 286.

#### *The Fermentation of Dextrose, Rhamnose, and Mannitol by Levulactic Ferment.* George Tate. *Proc. Chem. Soc.* 1893 [128], 203.

In studying the micro-organisms that attack ripe pears, the author has had occasion to isolate an organism that under

aerobic conditions brings about levulactic fermentations of the hexoses, dextrose, mannose and galactose and also of mannitol, but an inactive lactic fermentation of the methyl-pentose rhamnose (isodulcitol).

The products of the fermentation of dextrose, mannitol and rhamnose have been quantitatively determined: 9 molecules of dextrose are found to yield two molecules of alcohol, one of succinic acid, seven to eight of levulactic acid, the smaller molecular proportions of formic and acetic acids.

Mannitol yields the same products, but in different proportions, there being a greater yield of alcohol and slightly greater yield of levulactic acid.

Neither alcohol nor formic acid was found among the products of the fermentation of rhamnose; nine molecules of this sugar afforded approximately five molecules of acetic acid and four molecules of optically inactive lactic acid.

The action of the organism as a levulactic ferment of dextrose, was found to be unchanged after cultivating the parent cells in fluids containing rhamnose, inactive acid being formed.

The organism which is referred to as a levulactic ferment from its action upon the typical sugar dextrose belongs to the class of asco-bacteria, and can develop so as to produce two forms of growth, widely differing in macroscopic appearance—one in which rods and cocci predominate, a second in which the organism propagates as an asco-bacterium.

### PATENTS.

#### *An Improvement relating to the Process of Malting Grain.* A. Blake, Newport, Mon. Eng. Pat. 223, January 5, 1893.

LIME water, or lime and water, is used instead of ordinary water for steeping and sprinkling purposes.—J. G. W.

#### *Improvements in the Manufacture of Yeast.* F. M. Polsky, Paris. Eng. Pat. 1887, January 27, 1893.

RICE flour is mixed with double its weight of water at 70°—75° C., containing 6 grms. of calcium acid phosphate per kilo. of rice, and allowed to stand. Green barley malt, or a mixture of green barley and wheat malts, is then added, and the mixture again allowed to stand. Water at a temperature of 90°—95° C. is next added, until the temperature of the mixture reaches 62°—65°, and the resulting liquid is transferred to a vessel divided into several compartments. After cooling to not lower than 30°—32° C., yeast is now added, and subsequently and successively solutions of tartaric acid and potassium bicarbonate in several portions. Another lot of wort is then added, and finally ammonium carbonate or chloride. Fermentation is allowed to continue for six or eight hours, and the yeast removed. It is claimed that conducting the fermentation in a vessel divided into several compartments allows a large quantity of material to be dealt with, but yields better results than fermenting a large bulk at once.

—J. G. W.

#### *Improvements in the Treatment of Rice or other Grain for the Production therefrom of a Material suitable for Use in Brewing, or for other Purposes.* F. E. V. Baines, London. Eng. Pat. 4981, March 7, 1893.

RICE or other grain is digested with water containing lactic or sulphuric acid for half an hour at a temperature equivalent to 50 lb. steam pressure, in the proportions of one part of grain to seven parts of water containing 0.5 per cent. of lactic acid or 0.05 per cent. of strong sulphuric acid (sp. gr. 1.840). The digestion is stopped as soon as the product gives a reddish-brown colouration with iodine. The resulting solution is neutralised with milk of lime, filtered, concentrated, and applied to the surface of a steam-heated cylinder, upon which it is kept in a layer of equal thickness by means of cooled rollers. The dried product is then scraped off by means of spring steel scrapers. It is claimed that complete conversion of the

starch of the grain into dextrin is effected by this method and that the product can be reduced to powder, and will remain dry under ordinary atmospheric conditions.

—J. G. W.

*Improvements relating to the Clarification of Beer.* H. H. Lake, London. From K. Müller, Kehl, Baden. Eng. Pat. 5870, March 18, 1893.

Thin strips of aluminium of any convenient size are placed in the store casks, instead of chips of wood, to keep the sediment at the bottom.—J. G. W.

*Improvements in Apparatus for Cooling and Evaporating Liquids such as are used in Breweries and Distilleries, and for such like Purposes.* H. J. Worssam, London. Eng. Pat. 6316, March 24, 1893.

The apparatus described in this specification only differs from the vertical refrigerator in general use in breweries, in that there are two supply standards at each end, the pair on one side of the refrigerator being connected by the usual thin flattened tubes, as is the pair on the other side. The two pairs of standards and their attached tubes can be taken apart for cleansing purposes, and are so arranged that their tubes occupy alternate positions, so that when placed together they form a single, continuous, vertical series of tubes.—J. G. W.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY AND WATER PURIFICATION, DISINFECTANTS.

### (A).—CHEMISTRY OF FOODS.

*The Temperature of Bread during Baking.* A. Girard. Comptes rend. 1893, 117, 584.

The author states that 101° C. is the normal temperature of bread during baking and not merely the temperature sometimes attained, as was inadvertently stated in a recent note. (See Balland, this Journal, 1894, 55.)—A. K. M.

*The Influence of Mineral Antiseptics on the Lactic Fermentation.* A. Chassevant and C. Richet. Comptes rend. 1893, 117, 673–675.

In this paper the authors distinguish between the amount of an antiseptic required to check the multiplication of the ferment—to which action they apply the term *antigenetic*—and that required to arrest its functional activity—*antibiotic*. They have experimented with the salts of a number of metals, and their results are given in the following table:—

	Antigenetic.	Antibiotic.	Ratio, taking the First Column of Figures as Unity.
Magnesium .....	0.5	1.5	3
Lithium .....	0.25	0.5	2
Calcium .....	0.15	0.4	2.5
Strontium .....	0.125	0.25	2

	Antigenetic.	Antibiotic.	Ratio, taking the First Column of Figures as Unity.

—A. K. M.

*Milk, Skim Milk, and Whey: a Study of their Comparative Composition and Specific Gravity.* C. B. Cochran. J. Amer. Chem. Soc. 1893, 15, 247–251.

RICHMOND calculates that each gm. of albuminoids in 100 cc. of milk raises the sp. gr. 2.57 (*sic*), or that the density of albuminoid in milk is 1.346. Dupré shows that 1 per cent. of casein raises the specific gravity of milk 2.55, or that the density of casein in solution is 1.31; Hehner gives 1.3106 for the last-mentioned value.

The author has determined the total solids, fat, solids not fat, and specific gravity of a number of samples of skim milk, and has coagulated each sample with acetic acid or rennet at the temperature of a water bath. The total solids and specific gravity of the clear whey were ascertained and the difference between the total solids of the whey and the solids not fat of the skim milk was taken to represent the casein removed. The difference between the specific gravity of the skim milk and the whey, divided by the percentage of casein removed, represents the loss of specific gravity due to removal of 1 per cent. of casein. "The density of the casein in solution is found by the formula  $D-D^1 = \frac{1-x}{100x}$ ;  $D$  = specific gravity of whey;  $D^1$  = specific gravity of skim milk, minus all fat;  $x$  = effect of 1 per cent. of curd on density."

A table is given which embodies the results obtained by this method; the average calculated from them shows that each percentage of casein removed lowers the specific gravity of the solution 2.72, and that the density of the casein in solution is 1.376.

The solids coagulated by rennet and freed from fat were found to contain 1.08 per cent. of ash. When coagulation is properly performed under similar conditions, the specific gravity and total solids of whey of pure milk will vary within narrow limits. The specific gravity averages 1.027 and does not exceed 1.0285; the total solids vary between 6.5 and 6.9 per cent. If the whey be reheated, a further coagulation will take place, and the specific gravity be deduced to 1.028–1.0266. The specific gravity of the whey from a milk which had been allowed to decompose for 20 days was 1.0255. If the number representing the specific gravity of the whey above 1.000 be divided by 4.25, the quotient approximately represents the percentage of total solids in the whey.

The composition of whey does not materially differ whether it be derived from the original milk, the cream, or skim milk. Thus a knowledge of its composition may be

of value in determining a alteration, especially when the milk is in a churned or sour condition. The following table

serves to show the variation of the composition of the whey in samples of whole, skimmed, and watered milk :—

No.	Specific Gravity.	Total Solids.	Solids, not Fat.	Specific Gravity of Whey.	Total Solids of Whey.	
1	1.0307	11.32	8.78	1.0280	..	A partially creamed sample of milk.
2	1.0315	12.05	8.55	1.0270	..	Poor milk.
3	1.0273	10.99	7.50	1.0230	..	Watered milk.
4	1.0294	12.05	6.15	1.0213	..	Watered cream.
5	1.0.18	11.68	9.49	1.0255	5.89	Whey separated after milk had stood three weeks.
6	1.0310	12.05	8.45	1.0280	6.53	
7	1.0312	12.45	8.55	1.0270	6.35	
8	1.0320	12.90	8.80	1.0275	6.47	
9	1.0320	13.22	9.02	1.0273	6.42	
10	1.0324	12.98	8.83	1.0283	6.66	
11	1.0320	12.49	8.90	1.0270	6.35	
12	1.0278	8.81	8.71	1.0234	5.50	Watered skim milk.

*The Detection of Eosin in Coloured Tomatoes.* K. F. McElroy and W. D. Bigelow. J. Amer. Chem. Soc. 1893, 4, 191.

See under XXIII., page 284.

#### PATENTS.

*Improvements in the Preparation of Extracts of Tea and Coffee and in Utilising a By-product of the Process.* E. Soustalt, Churchfields. Eng. Pat. 6596, March 29, 1893.

THE inventor claims as chief improvement the removal of the tannin from tea or coffee extracts by addition of milk, and separates the insoluble tannin compound as a compact mass from the associated liquid by sterilising in a closed vessel. The milk, which may be skimmed, is added in suitable proportion to the extract, preferably during its concentration. The bulk of the tannate of casein readily separates in clots, which are afterwards made into a confection with sugar, or otherwise utilised. The proportion of milk is about 8 oz. to the extract from 1 lb. of tea, but the inventor does not confine himself to this proportion, as it naturally varies with the amount of tannin which it is intended to remove. When treating coffee extracts a considerable reduction is made in the proportion of milk.

—L. de K.

*An Improved Preparation of Malted Pulse Food.* M. Watson, London. Eng. Pat. 10,689, May 31, 1893.

THE invention claims the manufacture of nutritious digestible or partly digested foods from cooked leguminous seeds with malt, or a diastatic product from the same. The food may be further improved by the addition of oily or fatty leguminous matter. Pepsin, sugar, starchy matters, flavourings, essences, or alkali bicarbonates may also be added, but they form no part of the invention. Egyptian or Indian lentils are decorticated, soaked for 12 hours in water, and roasted until the unpleasant taste is removed and an appetising flavour is obtained. The product is then reduced to a flour and mixed with 5—35 per cent. of malted barley or oats. If it is desired to convert most of the starch, the compound may be treated with warm water or infusion of malt, and after some time be dried. Finally, half a per cent. of either sodium or potassium bicarbonate may be added, but this addition is not always desirable. To raise the proportion of albuminoids, ground roasted beans may be

added, but if it be desired to increase the quantity of oily matter only, ground roasted peannts should be used.

—L. de K.

*Improvements in and in Apparatus for the Manufacture of Margarine and Alimentary Fat.* J. Cordeweener and A. de Kunwald, France. Eng. Pat. 24,461, December 19, 1893.

THE patentees have constructed special appliances for the purpose of carrying out the process resulting from the combination of the following operations in the manufacture of margarine and alimentary fats:—(a) the physical union by cold of the constituent elements of the dry nonhydrated fatty matter; (b) the hydration, unification, bleaching, and odorification in the cold of the molecularly united fatty elements. In order to physically unite the non-emulsified elements, oleine, margarine, and stearine, constituting the fatty matters of various origins, these matters in a melted condition are placed in a container, from which they flow by gravitation through a pipe bent upwards at the base, and terminating in a rose inside a vessel containing liquid at a low temperature. The elements of the melted fatty matter, oleine, margarine, and stearine, being thus rapidly chilled, unite molecularly and float upwards to the surface of the refrigerating liquid. The congelation may be obtained either by means of cooled metallic surfaces, or by means of liquids or gaseous fluids. The congealed fatty matter thus obtained becomes, on standing, a translucent product of nacrous aspect. In order to hydrate and bleach this translucent product it is warmed to 20°—22° C. by showering on it liquid at that temperature, and is then transferred to a kind of churn with a perforated dasher. The semi-solid mass, which at the outset was yellow and translucent, is thus caused to pass through the perforations of the dasher, and becomes thereby transformed, without any appreciable elevation of temperature, into a whitish matter of creamy appearance. At this moment cream or milk is added for the purpose of incorporating in the mass the flavouring and odorous elements, which, by the action of the dasher, become intimately infused into the pores of the fatty matter. At this stage the product, if allowed to rest, would become brittle, to obviate which continued kneading is requisite; this, however, may be avoided by running it through a pipe into another churn with perforated dasher containing enough cold water to reduce its temperature to 12°—14° C. when the dasher is worked vigorously. The bottom of this churn is movable, so that the mass of factitious butter can be allowed to drop out into a truck with perforated bottom,

in which it drains without becoming brittle. Finally, it is kneaded to expel superfluous water, and then is said to possess all the visibly apparent qualities of natural butter.

—C. R. A. W.

### (B.)—SANITARY CHEMISTRY AND WATER PURIFICATION.

*Purification of Water.* Villon. *Revue Chim. Industrielle*, 1893, 87.

THE removal of calcium and magnesium sulphates and carbonates from potable and industrial waters, is generally effected by the addition thereto of caustic potash, sodium carbonate, or barium chloride. This method is, however, not only insufficient, because ammonium sulphate remains in the water, but it necessitates an exact estimation of the reagents and the use of costly apparatus.

The following electrolytic process is less costly and needs no surveillance, because the amount of the necessary reagents produced by the electric current is always equivalent to the compounds to be precipitated; no trace of the reagents remains in the water. The percentage of incrusting substances—the magnesium and calcium salts mentioned above—in the water, is determined in the usual manner, and the equivalent quantity of sodium nitrate is added, the water being thereafter submitted to the action of an electric current. Lead electrodes are employed. Caustic soda separates at the negative pole and nitric acid at the positive pole, which latter must be renewed from time to time. The last-named acid attacks the electrode, forming lead nitrate. Calcium and magnesium carbonates and sulphates are precipitated by the caustic soda, sodium sulphate and carbonate being formed; the sodium carbonate then precipitates the lead nitrate.

About 250 litres of water can be purified in an hour; and when 20 cubic metres of water are dealt with daily, the cost is not more than 5 centimes per cubic metre. The precipitates settle quickly, thus enabling the clear water to be drawn off.—A. R. L.

### PATENTS.

*Improvements in Filtering Sewage.* B. Rushford, Aldershot, and J. Edwards, Aldershot. Eng. Pat. 5689, March 16, 1893.

THE inventors claim as chief improvement a filtering-bed layer consisting of fine slag and small coal-dust screenings in equal proportions unwashed, with a small quantity of sulphate of iron.

The crude sewage is let into precipitating tanks and there treated, preferably with Gibb's alumina. The sewage water is then passed through layers of large gravel, broken gravel, shingle, coarse sand, fine sand, and then through the above filtering bed. Finally it passes through fine sharp sand.

The easing of the filter may be made of any impervious material. The filters may be constructed in series. A square foot of surface is capable of filtering about 2,500 gallons in 24 hours.—L. de K.

*Improvements in Apparatus for Softening Water.* C. E. Gittins. Eng. Pat. 8900, May 3, 1893.

A CLOSED vessel containing lime is fed with hard water, by a branch pipe from the rising main, and is thoroughly mixed with the lime by means of a stirrer, driven by a water motor, which latter is preferably actuated by the incoming water. The softened water afterwards flows away into the store cistern. Cut-off cocks are fitted on the inflow and outflow pipes to disconnect it for repairs, and suitable filling and cleaning orifices are provided on the mixing vessel.

—E. G. C.

*Improvements in or relating to Machinery or Apparatus for Treating, Deodorising, Drying, and Utilising, Excreta, Nightsoil, Town's Refuse, and the like.* S. Smithson. Eng. Pat. 23,082, December 1, 1893.

THE inventor claims as chief improvement the sorting, drying, and deodorising of town refuse by means of machinery. The refuse (excreta, nightsoil, &c.) is deposited in the hopper of a screen and passed through a screen, whereby the finer and useful portions are separated from the useless, which are then destroyed in a destructor. The useful portion is conveyed to and dried in a revolving cylinder, and caused to travel in an opposite direction to that from whence the heat proceeds. After drying, the material is passed through a second and finer screen to collect those portions which are useful for, say manurial purposes.—L. de K.

### (C.)—DISINFECTANTS.

#### PATENTS.

*Improvements in the Manufacture of Antiseptic and Disinfectant Materials for Sanitary Purposes.* C. R. Alder Wright, London. Eng. Pat. 1950, March 7, 1893.

THE inventor's claims are: I. An improved process for preparing monochloro- or bromonaphthalene fairly free from the higher halogen derivatives. II. The use of these compounds as antiseptic or germicide materials. III. The manufacture of disinfecting fluids by dissolving or suspending the said compounds in a solution of rosin soap, or in an emulsion of rosin oil in soap. IV. The manufacture of sanitary soaps by incorporating the naphthalene derivatives with ordinary soap. V. The manufacture of disinfecting powders by mixing the compounds with a suitable absorbent, such as sawdust, plaster of Paris, &c.

Monochlorinated naphthalene is prepared by suspending naphthalene in water contained in a suitable vessel provided with a cooling jacket and an efficient agitator. Chlorine, about 60 parts for every 100 parts of the hydrocarbon, is passed through, and the unaltered naphthalene is removed from the semi-solid mass by means of a current of steam. The monochlorine compound is left as an oily liquid, which may be directly used. The brominated compound is prepared in an analogous manner. Mixed compounds may also be produced.—L. de K.

*Improvements in Vessels for Containing Liquefied Sulphur Dioxide for Use as a Disinfectant and Vermin Destroyer, and for other Medical and Sanitary Purposes.* E. Soy, London. Eng. Pat. 12,276, June 23, 1893.

THE inventor claims to have constructed a vessel made of glass or other suitable material, which has a contracted orifice, through which it is filled with liquefied sulphur dioxide. The end is finally sealed in the flame of a blow-pipe.

The vessels are kept in a suitable box to prevent accidental breakage. When required for disinfecting a room, the box is opened and the tubes are struck with a hammer so as to break the glass. The room must then be at once left and the door sealed. The liquefied acid will rapidly resume its gaseous form and penetrate into every crevice of the floor, walls, and ceiling.—L. de K.

*Improvements in Disinfecting, and Apparatus for that Purpose.* E. Hermite, London, C. F. Cooper, London, and E. J. Patterson, London. Eng. Pat. 22,279, November 21, 1893.

THE inventors claim as chief improvement a method of disinfecting by conducting "electrolysed chloride solution" by pipes from a station to closets, urinals, and drains. The apparatus, a combination of a dynamo machine, electrolyser, and conductors, with suitable pumps, cisterns, pipes, cocks, &c., is minutely described and drawn in the original specification.

The process is carried out by charging reservoirs with sea water, or, if this is not available, with common water containing 10 kilos. of salt and 5 kilos. of commercial magnesium chloride per 1,000 litres. The liquid is now electrolysed until it contains about 2 grms. of free chlorine per litre, when it is diluted with six or seven times its bulk of water. The amount of chlorine being so small, the use of the liquid as a disinfectant is not attended with any unpleasant chlorine smell, whilst it destroys the unpleasant and noxious odour and effluvia of sewage matter.—L. de K.

Iou me.

—A. K. M.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*Note on the Liberation of Chlorine during the Heating of a Mixture of Potassium Chlorate and Manganese Peroxide.* Herbert McLeod, F.R.S. Proc. Chem. Soc. 1894, [133], 29—30.

In 1889 the author suggested an explanation of the catalytic action which takes place when an "oxygen mixture" is heated, an essential feature in the explanation being the evolution of a small quantity of chlorine; a few months later O. Brunck published in the *Berichte* a statement that the gas evolved together with oxygen is not chlorine but ozone (this Journal, 1894, 170).

The author has made several experiments to endeavour to solve the question. One test only was made for the presence of ozone in the gas, but it indicated that under the conditions of the experiment, ozone was not produced. In course of discussion Prof. Duostan remarked that the odour of the gas evolved from the mixture was more like that of an oxide of chlorine than chlorine itself. He inquired whether Prof. McLeod had ascertained whether a mixture of potassium chloride and manganic oxide furnished chlorine when heated in mercury vapour. If so, then not only the production of chlorine, but also of permanganate and alkali, from the chlorate, was susceptible of another explanation.

Prof. McLeod stated that he had not hitherto closely investigated this question.

*The Odoriferous Principle of the Violet.* F. Tiemann and P. Krüger. Comptes rend. 1893, 117, 548—552.

THE best known sources of the aroma of the violet are the fresh flowers of the violet and the dried orris root. The latter was chosen as being the source from which the odoriferous principle could be most readily obtained. The orris root is exhausted with ether and the ethereal extract is distilled in a current of steam. The product contains: (1) myristic acid, oleic acid, and other fatty acids; (2) the methylic ethers of the above acids; (3) traces of oleic aldehyde; (4) small quantities of neutral substances; and (5) *irone*. The last substance is the odoriferous principle of orris root, and is a ketone of the formula  $\text{C}_{13}\text{H}_{20}\text{O}$ ; it is an oil which is readily soluble in alcohol, ether, and chloroform. By the action of hydriodic acid on *irone*, a hydrocarbon *irone*,  $\text{C}_{13}\text{H}_{18}$ , has been obtained.

In an attempt to synthesise *irone*, the authors obtained an isomeric substance by the condensation of citral with acetone. This substance is named *pseudo-ionone*, and on treatment with dilute acids is converted into *ionone*,  $\text{C}_{13}\text{H}_{20}\text{O}$ , which likewise possesses and odour resembling that of violets. From this they have obtained a hydrocarbon *ionone*,  $\text{C}_{13}\text{H}_{18}$ , and some other derivatives.

The authors assign the following formulae to the two isomeric ketones:—

Iron.

*Irisin, the Glucoside of the Iris Root.* G. de Laire and F. Tiemann. J. Amer. Chem. Soc. 1893, 15, 351—355.

THE alcoholic extract of the powdered, dried rhizomes of *Iris florentina* is stirred with 2 litres of lukewarm water and 1 litre of a mixture of acetone and chloroform of 0.950 sp. gr.; the upper acetone-chloroform layer contains the substances of the alcoholic extract insoluble or only slightly soluble in water. The two layers are separated, the white flakes collected on a filter, washed with a little hot water, and dried at 100°. The white powder thus obtained is washed with ether and light petroleum, and crystallised from boiling dilute alcohol.

*Irisin*,  $\text{C}_{22}\text{H}_{34}\text{O}_{13}$ , crystallises in white needles, which become yellow in moist air and melt at 208°. It is moderately soluble in acetone, but hot alcohol is the best solvent for it. By hydrolysis it yields *D*-glucose and *Irogenin*,  $\text{C}_{20}\text{H}_{30}\text{O}_4$ , which crystallises in rhombohedra, melts at 186°, and dissolves in most solvents, particularly when warmed with them; it behaves as a phenol and is coloured violet by ferric chloride. *Dibenzoyl*- and *diacetyl*-derivatives were obtained.—A. G. B.

*Bulgarian Oil of Roses.* W. Markownikoff and A. Reformatsky. J. prakt. Chem. 48, 293—314.

THE authors have investigated three specimens of genuine oil of roses obtained through the Bulgarian Government. The chief constituents of oil of roses are elaeoptene and stearoptene, but the present paper deals principally with the former, to which is due the peculiar perfume of the oil. On freezing, the elaeoptene separates out from the oil in the crystalline form, whilst the stearoptene remains in the mother-liquor, from which it may be precipitated by the addition of alcohol. After repeated freezing (at  $-55^\circ\text{C}$ .) and fractional distillation, elaeoptene is obtained as a yellowish oil, boiling at  $222^\circ\text{—}222.5^\circ\text{C}$ . It rapidly oxidises on exposure to the air. The analysis agrees with the formula  $\text{C}_{10}\text{H}_{16}\text{O}$ . On treating with acetic anhydride it yields an acetate, and on oxidation with potassium permanganate a glycerin is formed. The molecular refraction of elaeoptene shows that it contains only one double bond, and in confirmation of this it was found that only two atoms of bromine add themselves on. The authors conclude that the chief constituent of elaeoptene is an alcohol having the above formula, for which they propose the name roseol. It belongs to the allyl alcohol series and is isomeric with the two known members of this series, allyldipropylcarbiol, b.p.  $192^\circ\text{C}$ ., and allyldipseudopropylcarbiol, b.p.  $169^\circ\text{—}171^\circ\text{C}$ . From its higher boiling point roseol is probably the normal alcohol. Oil of roses is thus closely related to some other ethereal oils. For example, Gladstone and Wright have shown that oil of citronella (*Andropogon nardus*) contains a substance,  $\text{C}_{10}\text{H}_{16}\text{O}$ , which Dodge proved was an aldehyde and that on reduction it gave an alcohol,  $\text{C}_{10}\text{H}_{20}\text{O}$ , boiling at  $225^\circ\text{—}230^\circ\text{C}$ , and possessing the smell of roses. According to Semmler's researches (Ber. 24, 201), oil of verbena (*Andropogon citratus*) contains an aldehyde identical with that obtained from oil of citronella. Indian oil of geranium (*Andropogon Schoenanthus*) also appears to contain a similar aldehyde. It seems quite possible that the valuable elaeoptene in oil of roses may be obtained from the much cheaper substances, oil of verbena and oil of citronella, and perhaps also by the reduction of geraniol. The rest of the paper is of a polemical nature, in which the authors declare that Eckhart's results (Ber. 24, 958 and 4205; this Journal, 1892, 265), which are not in agreement with their own, were likely obtained by experimenting on impure material, or through some adulteration in the oil of roses.—J. S.

*The Properties of Essential Oils, and their Employment in Painting Compared with that of Mineral Oils.* L. Lettenmayer. Chem. Zeit. 17, 1893, 1506.

In painting, essential oils are used for two purposes, either as simple diluents for oil pigments or as substances assisting in the drying of the other oils. If required for the first purpose only, oils free from or poor in terpenes, such as heavy camphor oil, clove, cajuput, or perhaps lavender, must be employed, or else oils containing terpenes which have been resinified. As driers, fresh turpentine or the light oil of camphor are the most suitable, as only those are available which yield a perfectly clear and transparent residue. The best resin solvents are turpentine, oil of rosemary, and the light camphor product, and these also, either alone or mixed with fresh nut oil, evaporate most quickly and completely, leaving only a small residue. Rectified oil of amber and wax oil lose by evaporation 50 per cent. in 24 hours, but leave after 75 days 20 per cent. and 40 per cent. of non-volatile matter respectively. The oils of cajuput and spike evaporate more slowly, leaving a small residue, while oil of lavender is the slowest. Heavy camphor oil and that from copaiba are useless, the latter gaining in weight on exposure. By means of petroleum, either the burning oil or a specially prepared product, the drying of the colours can be regulated to a nicety, but the residue, being soft and sticky and liable to turn brown in the air, renders the pictures liable to injury, and its use cannot be recommended, especially as it has the additional disadvantage of precipitating resins from their solutions.

The author advises the use either of rectified turpentine, light oil of camphor, or oil of rosemary when quick-setting paints are wanted, oil of lavender or spike being employed, either alone or mixed with the others, when slower drying products are preferred. In every case care must be taken that the oils are genuine and free from adulteration.

—F. H. L.

*The Preparation of Basic Organic Bismuth Salts.* A. Voswinkel. Pharm. Zeit. 1893, 33, 594.

*Basic bismuth gallate* is prepared by dissolving 100 grms. of bismuth chloride in a solution of 1,800 grms. of sodium chloride. To the filtrate, 400 grms. of gallic acid are added and the whole boiled for 20 minutes, the evaporated water being made up by the addition of more. The liquid is then poured into a large quantity of water so that an excess of gallic acid remains in solution. The precipitate, having the formula  $(\text{OH})_3\text{C}_6\text{H}_2\text{COO}.\text{Bi}(\text{OH})_2$ , is washed and dried.

*Basic bismuth pyrogallate* is prepared by dissolving 150 grms. of pyrogallol in a solution of 650 grms. of common salt, and adding a solution of 316 grms. of bismuth chloride dissolved in 1,000 grms. of common salt. The whole is heated on the water-bath for half an hour and poured into 20 times the amount of water. The formula of the compound is  $\text{OH}.\text{C}_6\text{H}_3.\text{OOBi}.\text{OH}$ . (This Journal, 1894, 171.)

—F. H. L.

*The Quantitative Estimation of Acetone and Salicylic Acid in "Sal Acetol."* H. Eckenroth and K. Kock. Also *ibid.* H. Helbing and F. W. Passmore. Pharm. Zeit. 1893, 38, 621.

See under XXIII., page 288.

*Contributions to the Knowledge of Albuminoses.*

H. Schrötter. Monatsh. f. Chem. 1893, 14, 612.

WHEN albuminous matters are decomposed by means of ferments, two classes of products are formed, distinguished as *peptones* and *albuminoses*. These are separable by saturating the liquid with ammonium sulphate, when the latter are precipitated, whilst the former remain in solution. By fractionally precipitating albuminose solutions with common salt, various more or less different substances are obtained, e.g., dys-, hetero-, proto-, and dentero albuminose. From the commercial manufactured article known as "*Peplone Witte*," the author has separated a variety of albuminose, soluble in alcohol, not distinctly crystallisable

therefrom, but exhibiting a microcrystalline structure, and forming a tolerably definite hydrochloride. Determinations of the molecular weight by Raoult's method give values lying between 587 and 711. On treatment with benzoyl chloride two benzoate ethers were formed, one containing sulphur, the other sulphur-free. C. R. A. W.

*Cresol as an Antiseptic.* Lacroix - Hunkialéyendian. Journ. Pharm. Chim. 28, 31.

Cresol is only slightly soluble in water, but its solubility in an aqueous solution of potassium cresol renders its employment as an antiseptic possible. This solution is named "*Solveol*." The cresol of coal-tar consists of a mixture of three isomerides, *o*, *m*, and *p* cresols, and this mixture has a greater action on micro-organisms than has either of the pure isomerides. The author has investigated the action of "*Solveol*" on putrescible matter, and considers it of great value in surgical work, having a strong antiseptic action, not affecting the hands and instruments, having a less unpleasant smell than phenol, and, in addition, giving a permanent, clear, neutral, aqueous solution, which does not solidify on cooling.—J. G. W.

*Isomers and Analogues of Aniligne.* G. N. Vis. J. prakt. Chem. 48, 24—30.

*Aniligne*, or *o*-ethoxy-*ana*-benzoyl-amidoquinoline, is formed by the reduction of ethoxynitroquinoline and treatment of the amido compound with caustic soda and benzoyl chloride. It is insoluble in water, but soluble in hot alcohol, from which it crystallises in small white crystals. It is used as an antineurotic. The corresponding methoxyl compound is prepared in a similar way, and possesses similar properties except that its salts are mostly easily soluble. It melts at 268—269° C.

*o*-Methoxy-*ana*-amidoquinoline is produced from the nitro compound by reduction with tin, stannous chloride, or iron, and hydrochloric acid. It crystallises from alcohol in yellow needles, m.p. 155°—156° C., and from water with 1 mol.  $\text{H}_2\text{O}$ , m.p. 76°. The acetyl compound is obtained by treatment of the free base with glacial acetic acid. From hot water it may be obtained in needles or in octahedral crystals, m.p. 179°.

*p*-Ethoxy-*ana*-nitro-quinoline, from *p*-ethoxy-quinoline by nitration, melts at 117° and is practically insoluble in water. The corresponding amido compound is soluble in hot water, yielding crystals with 1 mol.  $\text{H}_2\text{O}$ , m.p. 76°, the anhydrous base melting at 115°—116°. Acetylation gives a mono-acetyl derivative, which crystallises from hot water in white scales, m.p. 163°; the salts are soluble in water. The corresponding benzoyl compound melts at 144°, and is fairly soluble in alcohol, its salts being all soluble in water.

—J. W.

*On the Xanthine Bodies.* P. Balke. J. Prakt. Chem. 47, 537.

See under XXIII., page 284.

*Reactions and Constitution of Morphine.* G. N. Vis. J. Prakt. Chem. 47, 1893, 584.

See under XXIII., page 284.

*The Aerial Oxidation of Terpenes and Essential Oils.* C. T. Kingzett. Proc. Chem. Soc. 1894 [135], 51—52.

AFTER referring to his previous work on the subject, the author describes the results of an examination of a number of oily and semi-resinous products obtained on oxidising various turpentines by passing air either into the oil or into a mixture of the oil and water.

It is found that when any terpene is oxidised by air in the presence of water, or when the oxidised oil is shaken up with water, the aqueous solution always contains hydrogen

peroxide and a substance that may be obtained by evaporating off the water, this latter at the ordinary temperature of the atmosphere having the consistency of soft pitch, and being very bitter to the taste. Analyses are quoted of a considerable number of samples prepared from various oils, showing that the composition of the substance is approximately represented by the formula  $C_{10}H_{14}O_2$ . It appears to yield some cineol when distilled with dilute sulphuric acid. The oils which were found to yield this substance, and whether by oxidation alone or in presence of water, were Russian turpentine, American turpentine, camphor oil, several varieties of Eucalyptus oil, and an oil called "*Palustre*" obtained by the destructive distillation, at low temperatures, of *pinus taeda* and *pinus palustris* of the South Atlantic coast of the United States. (This Journal, 1890, 1005—1008.)

When Russian turpentine is oxidised in the presence of water and the aqueous solution is distilled, a small quantity of a light-yellow coloured oil passes over, which darkens on standing, and has a characteristic smell something like that of thymol. About 23 grms. of this oil were obtained by distilling 25 litres of the fluid. On analysis it gave numbers approximating to those corresponding with the formula  $C_{10}H_{14}O_2$ ; but on distilling this oil, after drying it over calcium chloride, only a portion passed over between 180 and 205°, leaving a viscous residue.

When oxidised Russian turpentine is evaporated down on the water-bath until all the volatile matter has apparently been driven off, and the residue is dried at 100°, a dark brown translucent mass is obtained, which, when cold, is quite hard and brittle; an analysis of this substance shows that it has a composition represented roughly by the formula  $C_{10}H_{14}O_2$ . Other oils afford somewhat similar results.

The author believes that in the limited oxidation (by air) of essential oils the terpene grouping is not broken down, as he has ascertained, by special investigation, that the acetic acid which sometimes accompanies the other products when the process is conducted in the presence of water, is not observed to be present if only pure or refined oils are employed, and he has not met with any product which can be assumed to contain less than 10 atoms of carbon in the molecule. See also this Journal, 1886, 7; 1888, 549; and 1890, 3.

## PATENTS.

*Improvements in the Manufacture of Salols.* H. Byk, Berlin, Germany. Eng. Pat. 23,419, December 20, 1892.

The patentee claims an improved process for obtaining salols (phenyl or naphthyl salicylates).

1. Salicylic acid (100 kilos.) is mixed with phosphoric anhydride (55 kilos.) in a closed iron boiler provided with a stirrer; the reaction is started by raising the mixture to a moderate temperature under a gentle pressure of carbonic acid gas. The source of heat is removed when the thermometer registers a temperature of 65° C., as otherwise the heat evolved in the reaction causes a rise of temperature above 100°, which acts deleteriously. Half an hour subsequently to this, the mass is heated at 90° C. for three hours, when the reaction is complete. Anhydrous phenol or naphthol is now added, whereby a rise in temperature of 15 to 20° C. is produced; the mixture is then stirred for an hour without further application of heat. The product is allowed to cool in earthenware vessels, where it separates into a deep red lower layer containing pyrophosphoric acid, and an upper pale-coloured paste consisting of the crystalline salol. When phosphoric anhydride alone is used, the pyro-phosphoric acid syrup separates with difficulty. "By the addition of 12 kilos. of syrupy phosphoric acid of sp. gr. 1.7 to 1.60 kilos. of salicylic acid, after preparing the boiler with a dressing of phenol, a good separation of the phosphoric acid from the salol paste is obtainable."

2. Meta-phosphoric acid (2 kilos.) is fused with salicylic acid (100 kilos.) and phenol (70 kilos.), a current of carbonic acid gas being passed through the mixture meanwhile. The boiler is then closed and the mass stirred for half an hour, after which the product is removed with hot water.

3. Salicylic acid and syrupy phosphoric acid of specific gravity 1.7 (100 kilos. of each) are heated with phenol (70 kilos.) in an open vessel for 6—7 hours; the mixture is kept stirred, and a current of carbonic acid gas is passed through it.

4. A quantity of a salicylate, equivalent to 100 kilos. of salicylic acid, is heated with 80 kilos. of phosphoric anhydride, 90 kilos. of meta-phosphoric acid, or 130 kilos. of syrupy phosphoric acid.

5. 100 kilos. of a mixture of equivalent quantities of sodium salicylate,  $C_6H_4(ONa)COONa$ , and phenol, is heated with 30 kilos. of phosphoric anhydride or 40 kilos. of syrupy phosphoric acid. Meta-phosphoric acid is not to be recommended on account of its high fusing point. The raw salol, separated from the aqueous stratum, is first washed with hot dilute soda, and then twice with hot water, to remove unaltered salicylate; the phenol is got rid of by blowing steam into the product; the crude salol is crys-tallised from alcohol.—A. R. L.

## *Manufacture of Salicylic Acid Ester of "Acetol."*

P. Fritsch, Ludwigshafen am Rhein, Germany. Eng. Pat. 3361, February 22, 1893.

MANY warnings have been raised, especially by Kohert and Hesselbach, against the use of salol for medicinal purposes, on the ground that phenol is set free from the compound in the human body and poisoning results therefrom. The patentee claims the manufacture the *salicylic acid ester of acetol*, i.e., the production of an ether of salicylic acid in which the latter is combined with a non-poisonous substance.

Sodium salicylate (180 parts) is suspended in alcohol (200 parts), and monochloroacetone (92.5 parts) added to the mixture, which is then heated in a reflux apparatus until the odour of monochloroacetone has disappeared. The following reaction takes place almost quantitatively:—

The reaction likewise occurs when the components are heated in aqueous or aqueous-alcoholic solution, and also, but with diminished yield, when the components are heated together without solvents. The new ester crystallises from alcohol in long woolly needles, melts at 71° C., is insoluble in cold water, and only sparingly soluble in hot water. A dilute solution of ammonia or of soda hydrolyses it with great facility.—A. R. L.

## *Manufacture of Compounds of p-Amidophenol Ethers and Aromatic Oxalaldehydes.* O. Imray, London. From the Society of Chemical Industry of Basel, Switzerland. Eng. Pat. 4191, February 25, 1893.

THE claims set forth in this specification comprise the manufacture of compounds of *p*-amidophenol ethers and aromatic oxalaldehydes, by two methods described below, as substances having in some cases valuable therapeutic properties; the latter is especially true of the compounds obtained by the action of salicylaldehyde on *p*-phenetidine or *p*-anisidine.

1. When a solution containing 23 parts of salicylaldehyde in 100 parts of alcohol is mixed with one of *p*-phenetidine containing 26 parts in 100 parts of alcohol, these being molecular proportions, the following reaction occurs:—

Heat is evolved, and at the end of two hours, there separates from the mixture a magma of yellow needles; these when recrystallised from alcohol melt at 90°—91° C. When, instead of *p*-phenetidine, *p*-anisidine is used, a similar compound is obtained which crystallises in yellow leaves and melts at 80°—82°.

2. These two compounds are also obtained when *o*-hydroxy-*p*-amidophenol, melting at 135° (see Ber. 1892,

25, 2754), is ethylated or methylated by boiling a solution of it in ethyl or methyl alcohol with the requisite amount of caustic alkali and ethyl bromide or methyl bromide.

—A. R. L.

*A Method of treating Tobacco or Tobacco Products to Prevent or Neutralise the Injurious Action of Nicotine contained therein.* H. H. Lake, London. From H. Gerold, Halle, and H. O. Wendt, Bremen, Germany. Eng. Pat. 4774, March 4, 1893.

Tobacco leaves are impregnated with a solution containing tannic acid and the essential oil of *origanum vulgare*, or with an infusion of oak bark and *herba origani vulgaris*, the proportion of the solution added being regulated according to the richness of the tobacco in nicotine. As soon as the leaves have absorbed the infusion they are lightly pressed and then dried with moderate heat. This treatment prevents the injurious dissolution and distillation of the nicotine.—C. A. K.

*Improvements in the Manufacture of Guaiacol.* J. Y. Thompson, London. From F. von Heyden, Nachfolger, Radebeul, near Dresden, Germany. Eng. Pat. 5284, March 11, 1893.

Impure guaiacol, or wood-tar, or materials containing guaiacol, are cooled by a freezing mixture, when pure guaiacol separates out, the impurities remaining liquid. The product thus separated is quite pure and is separated by pressing, centrifugal action, or other suitable means. The impure guaiacol can also be diluted, before cooling, by a neutral solvent, such as petroleum ether, and the pure product subsequently distilled, if necessary.—C. A. K.

*Improvements in the Manufacture of Piperazine and its Salts.* H. E. Newton, London. From the Farben-fabriken vormals F. Bayer and Co., Elberfeld, Germany. Eng. Pat. 5320, March 11, 1893.

PIPERAZINE is produced by boiling dinitrosodiphenyl-piperazine, which is obtained by the action of sodium nitrite upon diphenylpiperazine, with hydrochloric, sulphuric, or phosphoric acid. The use of sulphuric acid is claimed in a previous patent (Eng. Pat. 4497, March 7, 1892; this Journal, 1893, 463). The resulting solution is neutralised with alkali, filtered, an excess of alkali added, and the piperazine distilled over with steam. The piperazine or its salts are then obtained from the distillate in a suitable manner.—C. A. K.

*Process of Producing Esters from Creosote, Guaiacol, or Creosol.* C. D. Abel, London. From F. von Heyden, Nachfolger, Radebeul, near Dresden, Germany. Eng. Pat. 5856, March 18, 1893.

THE invention relates to the production of esters from creosote, guaiacol, or creosol with fatty acids, especially oleic and stearic acid, but also with other fatty acids, such as caprylic, capric, lauric, myristic, palmitic, arachidic, ricinoleic, linoleic, erucic, caproic, sebacic, &c. The esters are produced by the action of the phenols (or their salts) upon the fatty acids (or their salts) in the presence of dehydrating agents, such as the chlorides of phosphorus, or sulphur, or acid alkaline sulphates; or the acid chlorides of the fatty acids can be first prepared and these treated with the phenols. The resulting esters are liquids, insoluble in water, soluble in alcohol and ether; they are all devoid of the smell and taste of the phenols from which they are derived, and have no burning or caustic action on the mucous membranes. It is intended that they should replace the free phenols for medicinal purposes.—C. A. K.

*Manufacture of Production of Salols.* C. Kolbe, Radebeul, near Dresden, Germany. Eng. Pat. 6749, March 18, 1894.

THE patentee claims an extension of his previous patents for the manufacture of salols (Eng. Pat. 8018, June 16, 1886; 10,260, July 22, 1887; 13,169, September 12, 1888; 17,221, October 28, 1890. This Journal, 1886, 577; 1887, 561; 1888, 587; 1889, 817; and 1892, 58) to substituted phenols, the dehydrating agents employed being the same as previously claimed, with the addition of carbonyl chloride and of thionyl chloride. The substituted phenols employed are 1,2, 1,3, and 1,4-chloro-, bromo-, or iodo-phenol, 1,2,3 and 1,2,4-dibromo-, dichloro-, and diiodo-phenol, and trichloro-, trichloro-, and triiodo-phenol. The new compounds are colourless bodies insoluble in water, soluble in alcohol, which form salts with alkalis, and are separated on boiling with alkali. They possess advantages for therapeutic purposes over the ordinary salols, being free from smell and having only a slight taste, if any. The para-chlorophenol compound has the formula  $C_6H_4(OH)(CO_2OC_2H_5)$ .

—C. A. K.

*A Method for Producing Artificial Citric Acid.* A. L. C. Welmer, Hanover, Germany. Eng. Pat. 5620, November 2, 1893.

THE patentee claims the manufacture and method of producing artificial citric acid by the fermentation of carbohydrates, glycerol, and analogous substances, under the influence of certain fungi (organisms), particularly of two hyphomycetes discovered by himself and named *Citrifungus citricus*. The spores of these organisms, which are generally present in the air, develop with special facility into sugar-like substances in presence of small quantities of acid. Two species have been isolated in a state of purity. The organisms produce an intense citric acid fermentation in sugar solution; their separation is not necessary for industrial purposes.

To prepare these organisms, sugar solution containing 2—5 per cent. of citric acid is allowed to remain for a few days; the growth formed on this solution is introduced into sterilised sugar, where it develops. The "pure culture" prepared in this way is then introduced into large vessels containing a sugar solution in which is dissolved a small quantity of ammonium nitrate, dipotassium phosphate, and magnesium sulphate; the liquid is then allowed to remain at the ordinary temperature for 8—14 days. At the expiration of this time the liquid contains a certain amount of citric acid, so that it can be directly employed for human juice. The acid can also be isolated, and preferably in the form of a salt. For the latter purpose the liquid is neutralised with lime or carbonate of lime, or the latter or other convenient salts are added previously to the culture liquid, so that calcium citrate is precipitated as soon as the acid is formed.—A. R. L.

*An Improved Preparation of Ferrous Salts.* F. W. W. Clark, London. Eng. Pat. 22,931, November 29, 1893.

THE ferrous salt, either alone or mixed with other drugs which are prescribed with ferrous salts, is mixed with glyco-gelatin, a preparation of gelatin, glycerol, and water. Ferrous salts thus mixed are not readily oxidised when in contact with air.—C. A. K.

## XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

### PATENTS.

*An Improvement in the Manufacture of Photographic Plates.* O. Magerstedt, Berlin. Eng. Pat. 5932, March 20, 1893.

This invention has for its object to obviate the defect shown by negatives which have been exposed on subjects possessing much contrast, known as halation. The plate is coated with gelatin containing a dye in solution, of which the following are the most suitable:—The red colours of the rosaniline series and their sulphonic acids, those of the rosolic acid series, the reds and yellows of the aurine process, and the safranines, phosphines, uranines, &c. When this solution is dry the sensitive emulsion is applied as usual, and the dye will be completely removed from the negative either by the developer or the fixing bath, an acid one being preferably employed.—F. H. L.

*An Improved Method of Photographic Printing in Bromide of Silver.* E. Norden, Hatcham, S.E. Eng. Pat. 6491, March 27, 1893.

PAPER or other material is coated with a mixture of gelatin and a soluble bromide—with or without the addition of a small proportion of chloride. It is dried and floated in a solution of silver nitrate, dried again, and treated with a 20 per cent. solution of potassium oxalate. It forms a "printing-out" paper, or one not requiring development.—F. H. L.

*Hygroscopic Paint or Coating Material for keeping Packing Cases Dry.* C. D. Abel, London. From the Westfälisch-Anhaltischen Sprengstoff Actien Gesellschaft. Eng. Pat. 7571, April 13, 1893.

To avoid the expense of the metal-lined cases with soldered joints usually employed for packing hygroscopic goods which have to travel by sea, the inventors make use of an ordinary porous packing-case and coat it on the inside, either all over or only in one place, with a mixture of 30—40 parts of calcium chloride, 30—35 parts of glue, and 10—15 parts of an absorbent powder, such as infusorial earth. It is stated that the calcium chloride will absorb its six equivalents of water, and yet be retained in place by the glue and the infusorial earth. The inventors also claim the use of other deliquescent salts, other absorbents, and other binding materials.—F. H. L.

## XXII.—EXPLOSIVES, MATCHES, Etc.

*The Gelatin Explosives.* P. G. Salford. J. Amer. Chem. Soc. 1893, 15, 552—560.

The chief "gelatin" explosives are blasting gelatin, gelatin dynamite, and gelignite. They all consist of the variety of nitro-cellulose known as collodion-cotton (*i.e.*, the pentanitrated tetra-nitrates, the hexa-nitrate-cellulose being known as gun-cotton) dissolved in nitro-glycerol, and made up with various proportions of wood pulp, and some nitrate or other material of a similar nature.

Blasting gelatin has a specific gravity of 1.5—1.55, and consists of 92—93 per cent. of nitro-glycerol and 7—8 per cent. of nitro-cotton, of which the following is a typical analysis:—

Soluble nitro-cotton .....	59.118
Gun-cotton .....	0.612
Non-nitrated cotton .....	0.210
Nitrogen .....	11.64
Ash .....	0.25

"Collodion-cotton" is soluble in ether-alcohol, nitro-glycerol, and acetone; "gun-cotton" only in the last-named liquid. It follows that nitro-cotton used in the manufacture of gelatin compounds should be free from gun-cotton, and it is also important that the nitro-cotton should stand the Government heat test. It must be finely powdered and rubbed through a brass sieve by hand in the dry state. Its percentage of nitrogen should be over 11 per cent. Before incorporation with the nitro-glycerol, the nitro-cotton, which is generally transported wet in zinc-lined wooden boxes, must be dried, the progress of drying being determined by testing a sample at intervals by drying it in the water-oven. The product should contain not more than 0.5 per cent. of moisture, and in sifting and handling should be exposed to the air as little as possible, as it may take up some 2 per cent. of hygroscopic moisture. The drying house is usually a wooden building fitted with a framework to contain drawers of wood, the bottoms of which are made of brass or copper wire netting. The cotton is spread out on these to a depth of 2 in., and a warm current of air passed over it. If the building be itself heated by hot-water pipes, the pipes should be boxed in, as much dust from the nitro-cotton settles on all parts of the building. A temperature of 40° C. in the drying house is quite hot enough.

Gelatin dynamite and gelignite are manufactured in the same way as blasting gelatin. The following are typical analyses of the three compounds:—

	Blasting Gelatin.	Gelatin Dynamite.	Gelignite.
Nitro-glycerol .....	32.94	71.128	60.514
Nitro-cellulose .....	7.66	7.632	4.888
Wood pulp .....	..	4.259	7.178
Potassium nitrate .....	..	16.720	27.420

The preparation of blasting gelatin is effected by mixing dry nitro-cotton with pure dry nitro-glycerol in a lead-lined trough by stirring at a temperature of 40°—45° C. for half an hour until gelatinisation takes place. The jelly is mixed in a kneading machine (made of gun-metal) such as is used for bread. The preparation of the mixture of nitro-cotton and nitro-glycerol for the manufacture of gelatin dynamite and gelignite takes place in the same manner, the other ingredients (wood pulp and nitre) being afterwards incorporated. The application of heat in the manufacture of jelly from collodion-cotton and nitro-glycerol is necessary unless some solvent other than nitro-glycerol, *e.g.*, acetone, acetic ether, methyl, or ethyl alcohol, be employed. These solvents not only dissolve the nitro-cellulose in the cold, but also render the resulting explosive less sensitive to concussion, reduce its rapidity of explosion, and lower the freezing-point. The product, however obtained, is moulded in an apparatus like a sausage machine, the issuing rod of explosive being cut into lengths suitable for cartridges by means of a wooden wedge. The cartridges are required to pass the Government liquefaction test, which is carried out by cutting a cylinder of which the height is equal to the diameter, pinning it to a flat paper surface, and exposing it for 144 hours to a temperature of 85°—90° F., at the end of which time the cylinder should not have diminished in height by more than  $\frac{1}{8}$  in. and the cut edges should still be sharp. There should be no stain of nitro-glycerol upon the paper. The exudation test, which is also compulsory, consists in freezing and thawing the explosive three times, after which no exudation should be perceptible.

According to Berthelot, blasting gelatin containing 91.6 per cent. of nitro-glycerol and 8.4 per cent. of nitro-cellulose gives by explosion,  $177\text{CO}_2 + 143\text{H}_2\text{O} + 81\text{N}_2$ . The same authority gives 1,535 calories as the heat liberated by the explosion of 1 kilo. of blasting gelatin, and 8,950 litres as the corrected volume of gases liberated. Taking the explosive value of kieselguhr dynamite as unity, that of blasting gelatin is 1.4, and that of nitro-glycerol 1.45.

—B. B.

**Metallic Derivatives of Acetylene. Mercuric Acetylide.**  
M. Travers and R. T. Plimpton. *Proc. Chem. Soc.* 1894 [133], 32—33.

HERTELOR (*Ann. Chim. Phys.* [4], 9, 386), by passing acetylene through a solution of mercuric iodide in potassium iodide made alkaline with ammonia, obtained an explosive mercuric acetylide, of which, however, he seems to have made no analysis. The authors have prepared this substance in various ways, and studied its composition and properties. They have prepared it by the action of acetylene—(1) on freshly precipitated mercuric oxide; (2) on solutions of mercuric cyanide mixed with ammonia, or better, with ammonia and cupric sulphate or zinc chloride; (3) on solutions of mercuric acetate or sulphate with ammonia, when a part only of the mercury is precipitated; (4) on mercuric oxide dissolved by the aid of ammonia and ammonium carbonate. The latter method is the most convenient. The heavy white powder which separates is well washed and dried at 100°. Analysis indicated the formula  $3C_2HgH_2O$ . The substance could not be obtained free from water even after long drying at 100°. Mercuric acetylide belongs to the same class of bodies as the silver and copper acetylides, and it is explosive. It resembles the allylene derivatives obtained by Katscheroff from solutions of mercuric chloride and acetate (*Ber.* 17, 13). Mercuric acetylide detonates violently when suddenly heated or struck sharply; it can, however, be handled with safety even when dry.

## XXIII.—ANALYTICAL CHEMISTRY.

### APPARATUS, ETC.

**A Modification of the Litre Flask.** W. B. Giles.  
*Chem. News*, 69, 99—100.

In the preparation of solutions intended for use in volumetric analysis, it is of primary importance that the exact titre—or strength—be established before they are applied to the estimation of undetermined factors. In many cases this is effected by taking an exact weight of the reagent and dissolving it so that the solution may amount to exactly 1 litre in volume at the standard temperature. When this method is applied to such materials as potassium bichromate, silver nitrate, and similar reagents which are readily obtained in a state of almost chemical purity, it answers fairly well, although, to an accurate worker, it is preferable even in such cases to determine their actual reacting power by direct experiment. When, however, the nature of the reagent employed renders it difficult or impossible to obtain an exact quantity by direct weighing, a correction of the resulting standard solution becomes an absolute necessity, as is well known.

In working with such bodies as, e.g., sulphuric acid, thiocyanate of ammonium, or uranium nitrate, if normal solutions are desired, they must in the first instance be prepared too strong; and, after their exact working strength has been established by experiment, they must be reduced by the addition of more fluid to the normal strength. With the ordinary litre flask this involves some difficulties. Assuming that the solution has been made up to the mark, a certain portion must be withdrawn to determine the titre, leaving an odd number of cc. in the flask to be corrected after trial, even if a portion is poured into another smaller graduated measure, and some calculation is needed to determine the amount of fluid to be added.

The author has devised the modification shown in the figure. The measuring flask has an additional bulb blown upon its neck. Up to the ring marked B it holds exactly 1,000 cc. Above this is the bulb with another mark, A. Between these two marks the contents are 100 cc. To make any normal solution with these flasks, one-tenth more of the reagent is weighed out than would be used

with an ordinary flask, and the vessel is filled to mark A, always taking care that the resulting solution shall be *rather too strong*. After thorough mixing, enough is poured into a clean vessel to bring the fluid to mark B; thus there is obtained 100 cc. of solution for ascertaining

the exact titre, and exactly 1 litre is left in the measuring vessel for correction. In this way the calculation is much simplified, and the additional space afforded by the bulb facilitates the ready mixing of the fluid.

Some 2,000-cc. flasks made on the same principle have also proved useful. In this case the bulb holds 200 cc.

**Sampling by Quartation.** P. W. Shimer and S. K. Reifsnyder. *J. Amer. Chem. Soc.* 1893, 15, 260—265.

EXPERIMENTS as to the possibility of perfect sampling of a mixture of dissimilar substances by the methods commonly in use were made by mixing 500 grms. of lead shot, just large enough to be retained by a 10-mesh sieve, 500 grms. of magnetic iron ore of a size between a 10- and 20-mesh sieve, and 500 grms. of crushed glass, that had passed a 20-mesh sieve, and from which the finest powder had been removed by washing.

It was first demonstrated that sifting this mixture sufficed to recover 33½ per cent. (the amount used in making the mixture) of each ingredient. The constituents were again mixed, repeatedly quartated, and each diminishing fraction mechanically analysed by sifting, with the result that the sampling became increasingly inaccurate as the quartation was continued. Sampling moist was found to be slightly better than sampling dry, and flattening out the sample by pressure with a board, preferable to spreading it out by means of a spatula. Similar results were obtained with a crushed iron ore, which had been divided into four sizes by sifting. The method of halving the ore by allowing a scoopful to fall over a thin partition was tested, and found to be inferior to the more usual process of quartation. The authors arrive at the following conclusions:—

- (1.) It is more accurate to sample moist than dry.
- (2.) It is better to mix dry, than moisten and mix again before quartation.
- (3.) It is better to flatten the sample by pressure than to spread it with a spatula.—B. B.

**An Improved Laboratory Burner.** N. Teclu. *J. prakt. Chem.* 47, 535—536.

THE author has improved upon his former design for a laboratory burner so that the regulation of the air and gas occurs simultaneously. The accompanying figure represents his improved burner.

The plate *a*, for regulating the supply of air, moves vertically on a screw cut on the outside of the gas supply tube. Connected with this plate is a ring *b*, which rotates on the cylindrical foot of the burner. The ring is provided with an additional block *m*, which is cylindrical in the lower part and fits air-tight and obliquely into the tube which supplies the gas. There is a horizontal hole bored through the cylindrical part of the block *m*, and according to the position of the plate *a*, this hole will either wholly or partially

coincide with the opening in the gas-supply tube, so that the gas may have free or only a limited access to the burner.

This arrangement enables the gas to be burnt with the hottest possible flame of any size within the given limits. The character of the flame itself may be varied by means of the screw *c*, which when turned in one direction approaches, or in the other direction recedes, from the plate *a*, and regulates the supply of air.—J. S.

*Sulphuretted Hydrogen Apparatus.* F. W. Küster.  
J. prakt. Chem. 48, 595—598.

A, B, and C, in the figure are three bottles of 5, 3, and 10 litres capacity respectively, C being filled with ferrous sulphide in as large pieces as possible, whilst A and B are charged with a mixture of 2 vols. of crude hydrochloric acid and 1 vol. of water. The tube connecting A and B is drawn out to a fine jet at both ends, and its length determines the pressure obtainable from the apparatus. D

contains water, and serves both as a washing and safety bottle. E is charged with distilled water which becomes saturated with sulphuretted hydrogen, so that a supply of

sulphuretted hydrogen water can always be got from the tap at the bottom of the bottle. When gas is being drawn from the apparatus, the acid flows from A into B and thence, in drops or in a fine stream, into C. By the time the acid has trickled down to the bottom of the bottle C, it is completely exhausted, and the ferrous chloride solution may be drawn off by means of the tap when a large quantity has collected. When the tap between C and D is closed, the acid in B is partially forced back into A and the action ceases. The only attention the apparatus requires is when A requires filling with fresh acid, and C freeing from ferrous chloride. The small cut shows the method of distribution of the gas. One apparatus has been 10 years in use in the Marburg laboratory, without repair.—J. W.

*An Automatic Extractor for Phosphates.* W. D. Horne.  
J. Amer. Chem. Soc. 1893, 15, 270—272.

This apparatus is designed for the extraction of soluble phosphoric acid in the analysis of commercial fertilisers. The conventional plan of washing 2 grms. of the sample with repeated portions of 10 cc. of water until 250 cc. have run through is tedious to carry out by hand.

The apparatus consists of an inverted wide-mouthed bottle of 250 cc. capacity closed by a perforated cork carrying two glass tubes, one of which projects downwards 3—4 cm. and tapers to a fairly fine point. The other is bent upwards to the top of the bottle. By means of this device water under a constant head flows out of the shorter of the two tubes, air entering by the longer. The rate of flow can be adjusted to the capacity and permeability of the filter supplied by the bottle, by partially plugging the air inlet. The lower part of the apparatus consists of a syphon of variable length of limb, so that (1) the continuous flow from the bottle is converted into an intermittent discharge; and (2), the quantity of each discharge is suited to the capacity of the filter to be washed. The variable portion of the syphon may conveniently consist of a piece of rubber tube with an obliquely cut end to ensure its emptying at each discharge. The author states that it has been experimentally shown that the results obtained by this method of mechanical washing are identical with those arrived at when washing by hand is adopted.—B. B.

*New Tube for Polarimetric Observations.* F. Hann, Zeits. Zuckerind. Böhm. 18, 14.

The tube described has its inner portion widened at both extremities, the object of this being that if by chance air bubbles remain in the solution, they are not seen when the tube is placed in the apparatus, and do not, therefore, interfere with the observation.—A. R. L.

**INORGANIC CHEMISTRY.—**  
**QUANTITATIVE.**

*The Characteristics of Portland Cement.* R. Fresenius and W. Fresenius. Zeits. Anal. Chem. 32, 433—445.

See under IX., page 252.

*The Chemical and Physical Examination of Portland Cement.* T. B. Stillman. J. Amer. Chem. Soc. 1893, 15, 181—190.

The author attributes the fact that American cement is held in less esteem than that of German manufacture to the differences of the methods of testing in use for the two products. He gives the usual limits for the composition of Portland cement, and mentions that the main cementitious constituent is tricalcium silicate,  $3\text{CaSiO}_2$ . The following table shows the scheme of analysis adopted by the author for the analysis of Portland cement.

With regard to the mechanical tests, those of chief importance are the determination of fineness, the ascertainment of soundness, and the testing of tensile strength. The standard sieve in use in America appears to be that having 100 meshes per linear inch, made of No. 10 wire, Stubbs's wire gauge. The test for soundness is that usual in this country, namely, the observation of the behaviour of thin pans of neat cement kept under water and examined for cracks or other symptoms of internal strains. The tensile strength is determined on a mixture of one part by weight of cement to three of sand, and the mould is filled without ramming. Five briquettes are used for each test and only those breaking across their smallest section are included in the return of the test.

The testing machines in use in America are represented by two types. One is that known as the Fairbanks and is operated by running shot into the bucket at the end of the upper lever of the apparatus until the specimen breaks, when a valve automatically cuts off the supply of shot from the hopper above the bucket.

The bucket with its contents of shot is weighed on the machine itself by removing it from its position at the end of the upper lever, replacing it by a counterpoise, and suspending it below the large balance weight at the left of the instrument and counterbalancing it by the use of the steel-yard graduated on the upper lever.

The second testing machine is a single lever instrument known as the Riehle and is actuated by a handwheel, not being automatic like the Fairbanks. The upper lever is merely an indicator by means of which small movements of the beam may be detected.—B. B.

#### *The Electrolytic Separation of the Metals of the Second Group.* S. C. Schmecker. J. Amer. Chem. Soc. 1893, 4, 195—206.

THE author has endeavoured to find a general method for the separation of the metals forming acid oxides from those forming basic oxides of the second group. The lines worked upon were generally the use of solutions containing alkaline tartrates, and the device of keeping the arsenic (when that element was dealt with) in its higher state of oxidation.

*Copper from Tin.*—0.1087 gm. of tin was dissolved in hydrochloric acid, oxidised with bromine, evaporated to dryness, taken up with caustic soda, neutralised with tartaric acid and treated with 4 grms. of tartaric acid and then with 10 cc. of ammonia (sp. gr. 0.932). Ten cc. of a solution of copper sulphate containing 0.0999 gm. of copper were added, the whole transferred to a platinum dish, diluted to 175 cc. and electrolysed for 17 hours by a current yielding 0.4 cc. of electrolytic gas per minute. The copper found weighed 0.1001 gm.

*Copper from Arsenic, Tin, and Antimony.*—A solution was prepared containing 8 grms. of tartaric acid and 30 cc. of ammonia, and to this portions of solutions of arsenic antimony and tin, all in their highest state of oxidation and containing approximately 0.1 gm. of the metal apiece, were added. The quantity of copper added to this mixed solution was 0.1016 gm. and on diluting to 175 cc. and electrolysing for five hours with a current generating 0.8 cc. of gas per minute, the quantity of copper found was 0.1019 gm.

*Cadmium from Antimony.*—Similar solutions were used and the condition of experiment were also similar to those mentioned above. The quantity of cadmium taken was 0.0916 gm. and that found 0.0920 gm. The precipitated metal was in a somewhat spongy condition and needed care in washing.

*Cadmium from Tin.*—The method and results were similar in all respects to those of the previous separation. The use of a weak current (0.2 cc. of electrolytic gas per minute) favoured the obtaining of the cadmium in a compact state. The separation of cadmium from arsenic and from a mixed solution of arsenic antimony and tin, also succeeded, the prescription used previously being observed.

*Bismuth from Arsenic, Tin and Antimony.*—A solution of bismuth nitrate containing 0.0518 grms. of the metal was used in each experiment, and the use of tartaric acid and ammonia, as in former cases, resorted to. The separations were good and the bismuth was deposited in a compact form when a weak current was employed. Owing to the comparative ease with which the bismuth oxidised, rapid and careful washing was necessary and the use of alcohol after the first washing with water was requisite.

*Mercury from Tin, Antimony and Arsenic.*—Some difficulty was experienced in keeping the mercury in solution in the presence of much free ammonia, but it was overcome by adding the mercuric chloride used in the experiments to the tartaric acid solution before the addition of the ammonia, or, if the reverse order was chosen, by having the solution dilute and adding the mercuric solution with constant stirring. In separating mercury from any one of the three metals a deposit that is easy to wash is obtained, but when all three are present a portion of the mercury is finely divided, and has to be washed with great caution without decanting off the wash water closely. This makes the evaporation of the residual water by the heat of the hand very tedious, but it cannot well be avoided.—B. B.

#### *Investigation as to the Value of Borax as the Basis of Acidimetry.* T. Salzer. Zeits. anal. Chem. 32, 529—537. (Compare this Journal, 1893, 466.)

TIN difficulties which attended the use of borax solutions in acidimetry (see Mohr's *Lehrbuch der Titrimethode*, vol. 2, p. 102, 1st ed.) have now been overcome, and the author has made a series of test experiments, which show that the most suitable basis of volumetric analysis is a decinormal solution of borax. The chief advantages in using this standard solution are, that it is easily prepared pure, and that it is not so liable to absorb carbon dioxide from the air. Oxalic acid is preferably used as the standard acid.

The author formerly recommended the use of methyl orange as indicator when titrating with borax solutions. On closer investigation, however, he finds that methyl orange is advantageously employed only when estimating the strong mineral acids; in other cases it is much better to use litmus. Citric acid seems to form a compound with boric acid, and is therefore best estimated in the usual way with caustic potash and phenolphthalein.—J. S.

#### *The Volumetric Determination of Potassium Borofluoride.* F. Stolba. Chem. Zeit. Rep. 17, 1893, 250.

FOURNIER on the well-known reaction between alkaline carbonates and borofluorides at a red heat:—

the author has worked out a process for the acidimetric estimation of these compounds. The dried borofluoride is weighed out into a deep platinum crucible, and a known weight, at least four times that of the former, of sodium bicarbonate added, and the whole well mixed up. The crucible is heated gently until the carbonic acid has passed off, then ignited until the mass is in a state of complete fusion. It is then put into a large platinum basin, water added, boiled, and titrated with normal acid added a few drops at a time, using litmus or brazil-wood as an indicator. If the acid be added in large quantities at once, the original borofluoride will be regenerated. The amount of acid required for the sodium bicarbonate being known, the difference between that and the quantity required on titration gives the amount of borofluoride, each cc. being equivalent to 0.042037 gm. of the potassium salt. Results quoted by the author are satisfactory.—F. H. L.

#### *The Technical Estimation of Lead.* A. H. Low. J. Amer. Chem. Soc. 1893, 15, 548—552.

THE ordinary dry assay for lead is frequently erroneous, and a quick wet method for technical use would generally be preferable. Alexander's molybdate method is the shortest hitherto proposed, but the presence of lime causes

inaccuracies. The ferrocyanide process devised by the author is as quick as the molybdate method if the quantity of lime is small enough to be neglected, but a reliable method should be capable of dealing with all classes of ores, and the two following schemes of analysis satisfy this condition fairly well.

(1.) *Permanganate method.*—One gram. of ore is treated with 10 cc. of aqua regia in a 250 cc. flask, and after the attack is complete 10 cc. of strong sulphuric acid are added and heating continued over a naked flame until fumes of sulphuric acid are evolved. The contents of the flask is cooled, diluted with 50 cc. of water, heated to boiling, filtered, washed with dilute sulphuric acid (1:10), and rinsed into a beaker with 50 cc. of boiling ammonium chloride solution made by diluting a cold saturated solution with an equal bulk of water. The lead sulphate dissolves, and its solution is decanted into the original flask. The residue in the beaker, which may contain lead, is boiled with a few cc. of strong caustic soda, and to the solution dilute sulphuric acid is added, precipitating the lead as sulphate, which is then rinsed into the beaker containing the main part of the lead. The solution of the whole of the lead sulphate in the ammonium chloride at this stage of the process is not obligatory. Three pieces of sheet aluminium, each  $\frac{1}{16}$  in. thick by  $\frac{3}{4}$  in. wide and  $1\frac{1}{4}$  in. long, are placed in the solution, which is heated to boiling for five minutes. To ensure precipitation of the whole of the lead as metal the bulk of the solution should be kept small. The flask is filled with tap water, and the lead washed by decantation and dissolved by treatment with 5 cc. of a mixture of 1 part of strong nitric acid and 2 of distilled water. The solution is separated from the residual aluminium, made slightly alkaline with strong caustic soda solution, using phenolphthalein as an indicator, treated with 10 cc. of a cold saturated solution of oxalic acid, cooled, and filtered. The lead oxalate is titrated with potassium permanganate in presence of sulphuric acid. The permanganate solution is standardised by the use of iron, and the figure thus obtained, multiplied by the empirical factor, 1.888, which is best checked by each operator by carrying out the process on 0.3–0.4 gram. of pure lead reduced from the acetate. None of the ordinary constituents of lead ores interferes with the results of this method, which are said to be accurate to 0.1–0.2 per cent.

(2.) *Ferrocyanide method.*—The ore is attacked, converted into sulphates, and filtered as described under the permanganate method. The bulk of the lead sulphate is washed with 50 cc. of cold water into the original flask, and 10 cc. of cold saturated solution of ammonium carbonate added thereto. The mixture is heated to boiling, cooled, filtered through the same filter, the precipitate (of carbonate) washed, boiled with 5 cc. of glacial acetic acid, and 25 cc. of distilled water, the solution diluted with 100 cc. of cold distilled water, and titrated with potassium ferrocyanide, uranium acetate being used as an indicator. The titration is best effected by separating a portion after solution from the main quantity, and adding it after the end point has been passed in titrating the main portion, finishing with more caution. A second reserve portion may be used in the same way. A deduction of two drops from the reading of the burette is necessary to allow for the ferrocyanide needed for the end reaction. The ferrocyanide solution contains about 10 grms. per litre, and is standardised on 0.3–0.4 gram. of lead reduced from the acetate and carried through the whole process. To provide against the influence of bismuth and antimony, the basic sulphates of which might interfere, 10 cc. of dilute sulphuric acid (1:10) and 2 grms. of Rochelle salt may be added to the original solution of the ore after evaporation with sulphuric acid. 40 cc. of water, instead of 50 cc. as mentioned in the prescription, are then added, and the process continued as already described. The only influence of lime is that due to the solvent action of calcium acetate on uranium ferrocyanide, but ores with as much as 30 per cent. CaO may be thus assayed, provided complete reaction between the calcium sulphate and ammonium carbonate be secured.

—B. B.

*An Examination of the Ordinary Methods for the Estimation of Carbon in Iron.* A. Ledebur, *Chem. Zeit. Rep.* 17, 1893, 259.

As the result of a long continued investigation into the merits of the different processes for the estimation of carbon in iron, the author concludes that Sarason's method is the best, the iron, when free from graphite, being previously dissolved in copper sulphate, while if free carbon is present this preliminary treatment is unnecessary. On fitting up a new apparatus, care must be taken that the gas issuing from the potash tubes is as dry as when entering them, and it is well to boil the decomposing flasks, and also the sulphuric acid thoroughly with chromic acid before taking them into use. For the combustion of the hydrocarbons, either a capillary platinum tube or a glass tube filled with copper oxide may be employed, preference being given to the latter when oxidising grey cast irons directly by means of chromic acid. To avoid the danger of the production of sulphurous acid, a combustion tube filled with pumice and lead chromate may be inserted in the apparatus. As a check, the chlorine method, or for wrought iron Eggertz' colour test, may be used. None of the volumetric methods yet devised can be recommended.

For the estimation of the graphite, 1 gram. of the iron is dissolved in 25 cc. of nitric acid (sp. gr. 1.18) kept cold, in an Erlenmeyer flask, the mixture is then boiled gently on the sand bath for an hour, filtered through an ignited asbestos filter, washed and dried at 120–130° C. (100° C. is not high enough). The graphite is then burnt by igniting it first in a stream of air, and afterwards, for at least an hour and a quarter, in a current of oxygen.—F. H. L.

*Estimation of Chromium in Chromium Steel and Chromium Iron Ore.* J. Spüller and S. Korman, *Chem. Zeit.* 17, 1893, 1360–1412.

This paper is in continuation of the investigations already published (this Journal, 1893, 867), on the volumetric estimation of chromium in ferrochrome. The same principle has been applied to the estimation of chromium in chromium steel. The fusion of chrome iron ore with a mixture of caustic soda and sodium peroxide has also been more carefully studied.

The chromium steel is dissolved in dilute sulphuric acid, evaporated to dryness and fused with caustic soda and sodium peroxide. The whole of the chromium is thus converted into sodium chromate. The mass is digested with water, and after removing any sodium manganate or ferrate with peroxide, and decomposing excess of peroxide with carbonic acid, the solution is made up to a certain measure, filtered, and the chromium estimated volumetrically by "Schwarz" method.

Two samples of chromium steel were analysed. The chromium was estimated, both volumetrically, by the author's method, and gravimetrically, by J. Blau's method. The results were as follows:—

	Cr. Volumetric.	Cr. Gravimetric.
	Per Cent.	Per Cent.
No. 1 .....	1.35–1.40	1.43
" 2 .....	1.08–1.10	1.10

The volumetric estimation takes only about 3½ hours, and the presence of Wolfram does not affect the working. Attempts were made to fuse the steel direct with caustic soda and peroxide, but the results were not satisfactory owing to the difficulty in bringing the steel to a very fine powder.

Further trials in the analysis of chrome iron ore have satisfied the authors as to the efficacy of their process.

By using pure caustic soda and sodium peroxide, the method can be applied to the detecting and estimating chromium in different iron ores.—H. M.

*Separation of the Stannous Chloride Method for Titration of Iron.* R. W. Mahon. Amer. Chem. J. **15**, 360; Jour. Amer. Chem. Soc. 1893, 396.

This modification depends upon the fact that when stannous chloride solution is added to a boiling solution of ferric chloride, strongly acid with hydrochloric acid, and containing also some mercuric and platinum chlorides, the ferric iron is first reduced to the ferrous state, and then the next drop of stannous chloride in excess causes the formation of a cloud of mercurous chloride, which becomes darkened and at once rendered perceptible by finely divided mercury and platinum, which are further precipitated. This mixture of mercuric chloride and platinum chloride can therefore be used as an indicator. It can be made of such strength that one litre contains 0.05 gram of metallic platinum and 34.0 grms. of mercuric chloride, and 15 cc. of this solution is a suitable quantity to use in a test.—H. S. P.

*Estimation of Barium in the presence of Calcium and Magnesium.* F. W. Mar. Amer. Jour. of Science, **43**, 321; Zeits. Anal. Chem. **32**, 470—171.

This separation depends upon the insolubility of barium chloride and the solubility of the calcium and magnesium chlorides in concentrated hydrochloric acid. One part of barium chloride according to the author, is soluble in 20,000 parts of concentrated hydrochloric acid at the ordinary temperature. The addition of ether decreases the solubility to 1 part in 120,000.

The chlorides of the above name alkaline earth metals are dissolved in as little boiling water as possible, 24 cc. concentrated hydrochloric acid added drop by drop, and, after cooling, 5 cc. of absolute ether are added, and the whole is well stirred. The precipitate is allowed to settle for a few minutes and it is then transferred to an asbestos filter in a Gooch crucible and washed with concentrated hydrochloric acid containing about 10 per cent. of ether. The precipitate should not be allowed to stand for more than a minute or two before being filtered, as on standing a small loss is found. The washed barium chloride is first dried at a low temperature and afterwards at from 150—200° C. and weighed. The method gives good results with mixtures of barium and calcium chlorides in all proportions, but when more than 3 grms. of magnesium chloride in 20 cc. of the solution are present a reprecipitation of the barium chloride is recommended.—H. S. P.

*Separation of Strontium from Calcium.* P. E. Browning. Amer. Jour. of Science, **43**, 50; Zeits. Anal. Chem. **32**, 468—469.

This method depends upon the solubility of calcium nitrate and insolubility of strontium nitrate in boiling amyl alcohol. The aqueous solution of mixed strontium and calcium nitrates is evaporated to dryness in a beaker of about 100 cc. capacity and the residue taken up with the least possible quantity of water; 30 cc. of amyl alcohol are then added and boiled for a few minutes, until the water has been completely expelled and the alcohol has attained its normal boiling point (125—130° C.). The liquid is then decanted and filtered through an asbestos filter in a Gooch crucible and the residual strontium nitrate is washed with small quantities of boiled amyl alcohol. The amyl alcohol for washing is delivered from a small wash bottle, to the mouth tube of which a small calcium chloride tube is attached containing a plug of cotton wool to prevent any of the calcium chloride falling into the alcohol. The residue is then warmed gently to expel all the alcohol, and the strontium nitrate again dissolved in a few drops of water, a drop or two of nitric acid added and again evaporated to dryness. It is then re-dissolved in a few drops of water, and again precipitated by addition of 30 cc. of amyl alcohol and treated as before, this second precipitation being necessary to remove traces of calcium that go down in the first precipitate. The precipitate of strontium nitrate is now collected on the filter, washed with amyl alcohol, dried at 150° C. and weighed. Strontium nitrate is not completely soluble in amyl alcohol, and the amount of correction

to be made for its solubility, depends of course upon the quantity of alcohol remaining after boiling the precipitate in it. As however only a few minutes boiling is needed to expel the water, the author always had about 25 cc. of alcohol remaining. This quantity was found to retain 0.001 gram of strontium in solution. For every 30 cc. of alcohol used therefore an addition of 0.001 gram of strontium must be made to the weight of precipitate found, and also from the weight of calcium sulphate found in the solution after separation of the strontium, 0.0035 gram must be subtracted for each 30 cc. of alcohol used.

The calcium in the two filtrates may be determined by precipitation with sulphuric acid and ethyl alcohol, or the filtrates may be evaporated to a small volume, and transferred to a weighed platinum dish and evaporated to dryness and ignited. Sulphuric acid is then added, the evaporation to dryness and ignition repeated and the calcium weighed as sulphate. The latter method gives the more exact results.—H. S. P.

*Separation of Barium and Calcium.* P. E. Browning. Amer. Jour. of Science, **43**, 314; Zeits. Anal. Chem. **32**, 469—470.

This method depends upon the same principle as the same author's method for separating strontium and calcium (see preceding abstract), viz., the insolubility of barium nitrate in boiling amyl alcohol, whilst calcium nitrate is soluble in the same medium. The same process is carried out as already described in separating strontium and calcium, except that in the case of barium only one precipitation is needed and no correction requires to be made.—H. S. P.

*Estimation of Free Acid in Solutions of Per-Salts of the Heavy Metals.* F. Hoffmann. Chem. Zeit. **17**, 1318.

As an accurate method for estimating the free acid in copper sulphate solutions, in place of the unsatisfactory results of the ordinary methods, the author presents the following:—

By adding to a solution of copper sulphate containing free acid, yellow prussiate in excess of that required to precipitate the copper, the following reactions take place:—

So that an excess of ferrocyanide has no influence on the amount of free acid. But the solutions used must be so dilute that the ferrocyanic acid produced will not decompose.

A small quantity of copper solution, containing about 2—3 grms.  $\text{CuSO}_4$ , is precipitated by a small excess of yellow prussiate, made up to a certain volume, and allowed to settle. The clear solution is poured off, and titrated with standard alkali.

In presence of ferric salts, potassium sulphocyanide may be used to show the presence of free prussiate. On adding  $\text{KCNS}$  to the solution, iron sulphocyanide is formed, which dissolves in ether with a red colour. The copper is precipitated first by the prussiate, then the iron; so that as soon as the red colour of the ethereal solution disappears, all the copper and iron will have been precipitated.

The above method can be used for the per-salts of all the other heavy metals. In the case of lead, silver, zinc, &c., where the precipitates with prussiate are colourless, it is not necessary for the precipitate to settle, nor is an excess of prussiate harmful.

The author has used the above method for several years, and finds that it gives very accurate results in solutions of per-salts.

The effect of small quantities of proto-salts on the results is very slight, and may for technical purposes be overlooked.—H. M.

*Critical Studies of Methods for the Estimation of Sulphur.*

*II. L. Marchlewski. Zeits. Anal. Chem.* 1893, **32**, 463—411.

In continuation of a previous article (*Zeits. Anal. Chem.* 1892, **31**, 1—15; this Journal, 1893, 375—376), in which various direct and indirect methods of estimating sulphur, existing as sulphide were examined and criticised, the author now gives the results of his investigation of the gravimetric methods of Gröger (modified by Treadwell), Sauer (modified by Zulkowski), and the volumetric methods of Fohr and Klobukow. In the case of the two former methods, he used a pyrites as standard, which, according to an estimation made by Lunge's process, contained 53.28 per cent. of sulphur, and which, as pure  $\text{FeS}_2$  contains 53.33 per cent. of sulphur, may, therefore, be considered to be almost pure  $\text{FeS}_2$ . In the case of Fohr's method, he used the same Witkowitz slag-cement, containing 1.257 per cent. of sulphur, as he used in experimenting upon the methods noticed in his first article (*loc. cit.*).

*Method of Gröger* (*Ber. österreich. Chem. Gesellsch.* 1881, 2), modified by *Treadwell* (*Ber.* 24, 1937; this Journal, 1891, 951).—This method depends upon the conversion of the sulphides of iron existing in pyrites, into monosulphide, by heating the finely powdered substance with iron powder to redness, in an atmosphere of carbon dioxide. The monosulphide formed is then decomposed in a flask by hydrochloric acid, and the sulphuretted hydrogen that is evolved is conducted into a standardised solution of iodine, whereby a portion of the iodine is converted into hydriodic acid and sulphur is precipitated. The excess of iodine is then determined by titration, from which the amount of sulphur in the sample can be calculated.

The author finds that the results obtained when working with pyrites free from barium or lead sulphate are in close agreement with those given by Lunge's method (this Journal, 1889, 966; 1893, 292). But, as pointed out by Treadwell, the method is not applicable for the technical estimation of pyrites, because the insoluble sulphates (of barium, lead, &c.) existing in the pyrites are more or less acted upon, and reduced by ignition with iron powder. For the correct technical estimation of sulphur in pyrites, Lunge's method, or Treadwell's latest method (*Ber.* 1892, 2377; this Journal, 1893, 64), should be used.

The author also experimented to see if the sulphur in lead sulphate could be correctly estimated by the Gröger process, but the results obtained were not concordant, and were too low.

*Sauer's Method* (*Zeits. Anal. Chem.* 12, 32, 178), modified by *Zulkowski* (*Ber. oesterr. Chem. Gesellsch.* 1881; Dingler, 241).—Sauer's method is based upon the combustion of the sulphide in a stream of oxygen and the estimation of the sulphur oxides evolved. Various modifications of the process have been made (by Mixer, Zulkowski, Tschirikow, Jaansch, &c.), which chiefly differ from each other and the original in the nature of the absorbent used to retain the oxidised products of the combustion. Zulkowski employs a solution of caustic potash (free from sulphate) and potassium hypobromite, made by adding, drop by drop and whilst cooling, 100 grms. of bromine to an aqueous solution of 180 grms. of potassium hydrate. The solution is then made up to one litre, and 30 cc. suffice for estimating 0.5 grm. of sulphur. After the combustion of about 0.5 grm. of pyrites, using a combustion tube about 40 cm. long, the absorbing liquid is acidified with hydrochloric acid, boiled to expel bromine, and the sulphuric acid precipitated as barium sulphate. The author obtained by this process very satisfactory results with the sample of pyrites used as standard, but he considers it too tedious a method for adoption as a technical analytical process. Another drawback to it is that it is not practical to carry on several estimations at the same time, as can be done in processes not requiring a combustion furnace. It is useful for determining sulphur existing as sulphide in substances containing other non-volatile but soluble sulphur compounds, such as calcium sulphate. Zulkowski recommends it for estimating sulphur in spent oxide from gas purifiers. For this purpose he employs a

tube about 60 cm. long, drawn out to a fine tube at the end at which the connection with the absorption apparatus is made, and also somewhat narrowed at a point near this end. A layer of platinised asbestos, 20 to 25 cm. long, is first placed in the tube, and shaken down to the constricted part, then at a distance of 7—10 cm. is placed a porcelain boat containing about 0.4 grm. of the gas oxide. The platinised asbestos is first heated, and moist oxygen led through the tube at the same time. After this the gas oxide is heated, beginning with the end nearest the platinised asbestos, and continuing the heating gradually towards the end at which the oxygen enters. The author does not state whether he finds the process satisfactory or not in the case of gas oxide.

*Volumetric Methods of Fohr* (*Chem. tech. Zeitung*, 1887, 195), and *von Klobukow* (*Ber.* 18, 1861; this Journal, 1885, 613). Fohr's method is one of the many methods for determining sulphur existing as sulphides, depending upon the decomposition of the sulphides with an acid, and estimation of the sulphuretted hydrogen evolved. In this instance the sulphuretted hydrogen is absorbed by an ammoniacal solution of zinc, then the absorbing liquid together with the precipitated zinc sulphide is saturated directly with a dilute cold solution of ferric sulphate in sulphuric acid, and the reduced ferrous salt titrated with permanganate. The author did not obtain satisfactory results with this method.

Neither did he find von Klobukow's method of any value. This was suggested for estimating sulphur in the higher sulphides, which when treated with acid, besides liberating sulphuretted hydrogen, precipitate sulphur, as also in the hyposulphites, sulphites, &c. The process attempts the conversion of all the elementary precipitated sulphur into sulphuretted hydrogen, by decomposing the substance mixed with zinc, by means of hydrochloric acid, and boiling to expel the sulphuretted hydrogen; but in the event of sulphur separating, the flask is cooled, allowed to stand and again boiled, and so on until the sulphur is removed. The author tested the method with a solution of polysulphide of potassium and with sodium sulphite, but in every case sulphur separated which could not be completely removed, and the results were too low.—H. S. P.

#### *Estimation of Sulphur in recovered Gas-purifying Material.* F. Meyer, *Chem. Zeit.* 17, 1319.

The method recommended by "Post" in his chemisch-technische analyse is very tedious. The following has been found much more convenient.

20—30 cc. carbon disulphide are introduced into a flask A, of about 150 cc., with which a small calcium chloride tube B is connected. In the bulb of this tube are placed 2—3 grms. of the purifying material, dried and wrapped in filter paper. The tube is then connected with a reflex condenser.

Instead of the calcium chloride tube B, a Soxhlet's extraction apparatus may be used.

When titred up in this way, the flask is heated on a water bath at about  $80^{\circ}\text{C}$ ., until the drops falling back into the flask appear quite colourless ( $\frac{1}{2}$  hour to 1 hour). The carbon disulphide is then distilled off, the last traces being removed by blowing air into the flask. The sulphur which remains, is oxidised with fuming nitric acid and a little potassium chlorate. The nitric acid is driven off with hydrochloric, and the sulphuric acid precipitated with barium chloride.—H. M.

### ORGANIC CHEMISTRY.—QUALITATIVE.

*Reactions and Constitution of Morphine.* G. N. Vis.  
J. prakt. Chem. **47** (1893) 584—587.

- (1.) The nitrogen-atom in morphine is methylated.
- (2.) Morphine is a tertiary base.
- (3.) By certain reactions morphine yields pyridine: hence it probably contains the pyridine-nucleus.
- (4.) Morphine derivatives are frequently known to become converted into those of the coal tar hydrocarbon, phenanthrene; if morphine does not therefore already contain the phenanthrene nucleus, it must at any rate be capable of producing it with great ease.
- (5.) When oxidised in a suitable manner morphine yields picric acid, and when fused with caustic alkali it yields protocatechic acid. Both reactions point to the existence of a benzene-ring in morphine. The second reaction indicates that morphine has a constitution analogous to that of papaverine, which also yields protocatechic acid when fused with alkali.
- (6.) Morphine contains two phenol hydroxyls, one of which behaves as a normal phenol hydroxyl whilst the other appears to behave as an alcohol hydroxyl. The third oxygen atom in morphine is of a neutral character.—D. E. J.

*The Detection of Eosin in Coloured Tomatoes.* K. P. McElroy and W. D. Bigelow. J. Amer. Chem. Soc. 1893, **4**, 191—195.

A SAMPLE of "tomato colour" made in Cincinnati was identified as an aqueous solution of bromeosin. Other articles of food have been known to be coloured with this and similar synthetic colouring matters, but hitherto the fact has not been recorded in the case of tomatoes. A method was elaborated for the detection of this colouring matter, the plan finally adopted being as follows. The solid portion of the tinned fruit is strained off and the juice is acidulated with hydrochloric acid and shaken out with ether. The ethereal solution is washed and shaken up with a dilute solution of caustic soda. Should this solution be strongly coloured it is acidified and extracted with ether, and the ether shaken out with caustic alkali as before, the operations being repeated until the colouring matter other than that sought has been eliminated. The fact that the natural colouring matter of tomatoes is not completely separated from its acid solution by ether nor removed wholly from ether by alkali allows of its separation from the artificial dyestuff by repeated treatment. The presence of a yellow-green fluorescence in the final alkali extract is indicative of bromeosin. As iodeosin does not give a fluorescence in alkaline solution its presence has to be determined by an additional test. The alkaline liquid resulting from the final extraction is gently warmed with sodium amalgam, and to it is then added a drop or two of very dilute solution of potassium permanganate. The presence of either iodeosin or bromeosin is indicated by the development of a green fluorescence.—B. B.

*On the Xanthine Bodies.* P. Balke. Journ. prakt. Chem. **47**, (1893), 537—567.

The author has investigated the effects produced by various reagents upon xanthine compounds, and the results are given in the following table:—

	Solubility in Water.	Action of Concentrated Caustic Soda Solution.	Action of Lead Acetate and Ammonia.	Action of Copper Acetate.	Fehling's Solution and $\text{NH}_4\text{OH}$ , $\text{HCl}$ .	Phosphomolybdic Acid.	Mercuric Chloride.	Silver Nitrate.	Picric Acid.	Weidel's Test. Evaporated with $\text{HNO}_3$ and $\text{Cl}$ water, and introduced into an Atmosphere of Ammonia.	Xanthine Reaction. Evaporated with $\text{HNO}_3$ .
1. Uric acid..	Almost insol.	$\text{C}_4\text{H}_3\text{N}_3\text{O}_6\text{H}_2\text{O}$ with difficulty sol.	..	..	..	..	..	..	..	..	..

*Tests of Purity of Rectified Wood Vinegar.* G. Buchner. (Chem. Zeit. **17**, 1319.)

THE German "Pharmacopœia," edition III., requires that 10 cc. rectified wood acetic acid decolorise 100 cc. permanganate solution (1 cc. = 0.1 grm.  $\text{KMnO}_4$ ).

The author has found that the reduction of the permanganate is due to creosote (guaiacol, cresol, &c.) contained in the acid. The other constituents, acetic acid, methyl alcohol, acetone, &c., decolorise permanganate solution only very slightly.

1 cc. of a 1 per cent. solution of creosote in acetic acid immediately decolorises 20 cc. of permanganate solution, so that what the Pharmacopœia demands is a minimum of 0.5 per cent. creosote in rectified wood vinegar. As the acid varies so much in composition, it is suggested that it would be more expedient to substitute an acid containing a fixed percentage of creosote.—H. M.

## ORGANIC CHEMISTRY.—QUANTITATIVE.

*Evaluation of Glue-stuffs.* F. Gautier. Zeits. Anal. Chem. **32**, 113—115.

THE value of glue-making materials, more especially of tanners' spetches, is not only dependent upon the absolute amount of glue-making substance, but also upon the relation existing between this and the non glue-making constituents of the raw material. These latter, which may be here regarded as impurities, are of two kinds,—the coarse impurities insoluble in water, such as sand, carbonate of lime, and fat; and those impurities that are soluble in water. In spetches therefore there are three things to be estimated; 1, the coarse impurities insoluble in water; 2, the raw glue, *i.e.*, the sum of the constituents soluble in water; and 3, the actual glue-yielding substance, *i.e.*, the pure glue.

If spetches be boiled with water, and the solution allowed to clear itself by standing, the insoluble matters, such as sand, carbonate of lime, &c., settle to the bottom, the fat floats on the surface, and the crude glue-making extract remains in solution. The latter when evaporated to dryness gives the raw glue. This can now be separated into matter precipitated from solution by tannin, *i.e.*, the pure glue-making constituents, and soluble impurities not precipitated by tannin. To estimate the pure glue-making constituents the amount of ash in the raw glue and in the tannin precipitate must also be determined. The process is as follows:—100 grms. of the sample are boiled in an evaporation dish with 1 litre of water and a few drops of caustic soda solution, until the extraction is complete. The solution is poured into a suitable vessel, made up to 2 litres, and allowed to settle for 10 hours. 20 cc. (= 1 grm. of the sample) of the clear extract are then evaporated to dryness, dried at  $105^\circ\text{C}$ ., and the dry residue weighed. It is then incinerated and the ash weighed. This gives the amount of ash-free raw glue. A further quantity of 20 cc. of the clear extract are then measured into a 100 cc. graduated flask, diluted with about 30 cc. of water, neutralised with acetic acid, and a solution of tannin added until a precipitate ceases to be formed; the liquid is then shaken, and its volume made up to 100 cc. It is then filtered on a dry filter, and a sufficient quantity of hide powder is added to the filtrate to precipitate the small excess of tannin that has been added, and the precipitate allowed to settle during ten hours. If the solution at the end of this time gives no indication of tannin in solution it is again filtered on a dry filter, and 50 cc. (= 0.5 grm. of the sample) are evaporated to dryness, weighed, and the ash determined by incinerating and weighing. This gives the amount of ash-free substance in the extract not precipitated by tannin, and by deducting this from the amount of ash-free raw glue, the amount of pure glue-making material is found. As an example:—

1. 20 cc. of extract (= 1 grm. of the sample) give—

0.760 grm. dry residue.

0.133 grm. ash.

0.627 grm. ash-free residue.

= 62.7 per cent. ash-free raw glue.

2. 20 cc. precipitated with tannin, made up to 100 cc., filtered, and excess of tannin removed and filtered. 50 cc. of filtrate (= 0.5 grm. of sample) give

0.054 grm. dry residue.

0.044 grm. ash.

0.010 grm. ash-free residue.

= 1.20 per cent. ash-free non glue-making substance.

Deducting (2) from (1): 62.7 — 1.2 = 58.5 per cent. pure glue; and the sample of spetch contains therefore—

58.5 per cent. pure glue-making material.

1.2 " non glue-making material.

13.3 " ash.

56.0 " of raw glue.

*Estimation of the Quantity of Juice contained in Beetroots.* A. Vivien. Bull. de l'Assoc. des Chim. **10**, 833.

See under XVI., page 264.

*Quantitative Colorimetric Estimation of Carbohydrates.*

E. Neitzel. Neue Zeits. Rubenzucker Ind. **32**, 13.

THE method which forms the subject of a German patent (72,982 of 1892), depends upon the reactions described by Ili (Chem. Zeit., 1885, **9**, 231; this Journal, 1887, 306, and 455), and by Molisch (Silzber. Wien. Akad., 6 Mai, 1886; this Journal, 1887, 149), namely, that when carbohydrates are heated alone, treated with acids, or dehydrating agents humus substances are formed which give rise to colorations when treated with aromatic compounds—phenols, alcohols, and amines.

The liquid in which the carbohydrate is dissolved or suspended is measured into a test tube and a known volume of an alcoholic solution of the aromatic compound added to it, and subsequently sulphuric acid, when on shaking the mixture together a coloration is developed varying in intensity with the amount of carbohydrate present. The coloration reaches its maximum only after the lapse of several minutes.

The point observed is the interval which elapses, when, after shaking together the mixture, a ray of light, which at first penetrates the solution is no longer able to do so. This is proportional to the percentage of carbohydrate. A table is constructed on tests carried out with solutions containing known amounts of sugar, and from it the percentage of sugar in a solution of unknown strength can be ascertained by again carrying out an experiment with it under the standard conditions.

The following precautions are to be observed:—The ray of light must be of constant intensity; the distance of the observer from the source of light must always be the same; the width of the test tubes employed must be equal.

The method serves for the estimation of sugar in drainage waters of the sugar factory, in urine, wine and beer.

—A. R. L.

*Rectified Wood Vinegar.* W. Brandes. Apoth. Zeit. **1893**, **8**, 534.

IT is required in Germany that 10 cc. of rectified wood vinegar shall immediately decolorise 100 cc. of potassium permanganate solution (1 in 1000).

The author finds that, owing to the simultaneous formation of manganese hydrate, it is difficult to decide as to this point, and recommends the addition of 10 cc. of dilute sulphuric acid to the permanganate solution before the addition of the wood acid.—J. G. W.

*The Oxygen Absorption, Acid and Iodine Numbers of various drying Oils.* L. Lettenmayer. Chem. Zeit. **17**, 1506.

See under XII., page 258.

*The Analysis of Lubricating Oils containing blown Rape Oil and blown Cotton Seed Oil.* T. B. Stillman. J. Amer. Chem. Soc. 1893, 15, 265-270.

The author states that a difficulty arises in the analysis of mixed lubricating oils when it is required that the specific gravity of the mineral oil that has been used should be ascertained, as the oil recovered from the ethereal extract of the products of saponification of the mixed oil is not necessarily identical in specific gravity with that which was originally taken. The determination of the nature of the fatty oil and the calculation of the specific gravity of the mineral oil from that of the mixture and that of the fatty oil are preferable for this purpose.

The large variation in the specific gravity of blown rape oil (0.930-0.960) makes the method useless when the lubricating mixed oil has been prepared with blown rape oil, but some information can be obtained by comparing the properties (notably the viscosity) of different mixtures of blown oil of known specific gravity and mineral oil, with those of the sample under examination.

The use of blown rape oil is said to be diminishing in favour of that of blown cotton seed oil—which is less liable than the unblown oil to develop acidity. The effect of blowing of the two oils on their iodine absorption is shown below—

	Iodine Absorption.
Cotton-seed oil.....	104-114
Blown cotton-seed oil.....	93-103
Rape oil.....	102-104
Blown rape oil.....	94-100

See under XII., page 257.

*The Estimation of Paraffins.* R. Holand. Chem. Zeit. 17, 1833, 1473 and 1483-1484.

THE estimation of the amount of solid hydrocarbons or paraffins in oils is a problem of considerable importance, particularly to those engaged in the brown-coal tar trade. The paraffin is the most valuable constituent of this substance, and the various oils obtained on distilling it are cooled and pressed most carefully to extract every possible trace of solid matter. The first pressing takes place at the temperature of spring water—yielding hard paraffin, the second and third are conducted at the ordinary winter temperature, and at an artificially lowered one respectively—yielding softer products; and all the resulting press cakes and oils have to be tested to determine their commercial value.

The oldest process for this estimation is Grotowsky's modified by Engler and Bohm, and consists in dissolving the oil in the smallest possible amount of ether in the cold and precipitating the paraffins by means of absolute ethyl alcohol. The precipitate is filtered off, washed and more alcohol added repeatedly until oil begins to be thrown out, and the precipitates must be redissolved and precipitated to free them from oil. The author's experiments show that this process is not sufficiently exact, the paraffins still containing oil and *vice versa*, besides occupying too much time. Pawlewski and Filemonowicz working on petroleum and ozokerite products, precipitate the paraffins from their solutions by adding 10-20 times their volume of glacial acetic acid, washing the precipitate finally with ethyl alcohol of 75 Tr. This process is useless for brown coal tar as the softer paraffins are somewhat soluble in the liquid. Zalzieski (this Journal, 1888, 349) dissolves the oil to be tested in five times its quantity of amyl alcohol and precipitates the paraffins by the addition of the same amount of ethyl alcohol of 75 Tr., keeping the mixture

for several hours at a temperature not exceeding 4° C. with occasional agitation, filtering off the precipitate through a cold dry paper, and washing with a well-cooled mixture of two parts of amyl and one of ethyl alcohol. He then dissolves the paraffins in ether, evaporates and dries the residue at 125° C. For oils containing little paraffin, he uses ten times the amount of the alcohol mixture, and allows it to stand 10-12 hours. Modified somewhat to suit the brown coal tar products, this process has only the disadvantage attending the use of such a high temperature for drying, beside the unpleasantness of the operation.

While ethyl alcohol of not more than 98 per cent. strength only yields turbid solutions with brown coal tar oils, 99.5-100 per cent. alcohol dissolves in all proportions these oils when free from paraffin up to the specific gravity 0.850; from 0.850 to 0.880 they require five times, and from 0.880 upwards ten times their weight of solvent, and all the solutions may be cooled to the ordinary laboratory temperature without any separation taking place. On the other hand paraffin of 60° C. melting point when boiled with alcohol, separates out all but slight traces when the liquid is cooled to 25° C., and at 0° C. it is absolutely insoluble. Softer paraffins are more soluble as their melting point falls, but even that melting at 34° is absolutely insoluble in alcohol at 0°.

In his paper the author gives a number of experiments carried out on various known mixtures of paraffins and paraffin-free oils, by dissolving 20 grms. of the substance in 100 cc. of absolute ethyl alcohol, cooling the solution for two hours in melting ice and filtering through a double filter, which show very gratifying results; the extracted paraffins having within a degree or two the same melting point as the original, and the oils on distillation remaining liquid up to the very last when the distillate was allowed to fall on a piece of ice, proving that they were perfectly separated; a result which he has never been able to obtain by Zalzieski's method. The experiments being only conducted on brown coal tar products, the author expresses a hope that other investigators will take up the matter in other directions.—F. H. L.

*The Determination of Malic Acid in Wines, &c.* C. Mücke. Zeits. d. allgemeinen österr. Apotheker ver. 30, 289. Zeits. Anal. Chem. 32, 481.

THIS article is an expansion of the author's previous paper on the separation of malic acid from succinic, citric and tartaric acids (Zeits. Anal. Chem. 31, 465), and describes in what way his original method should be modified in order to the estimation of malic acid in wine. The extractive matters and inorganic acids present in wine, are in part precipitated along with the malic acid when wine is treated with lead acetate and alcohol. To obviate this the process is modified so as to partly remove by precipitation and partly to decompose these interfering substances. The tanning and colouring matters in the wine in particular are acted upon so that ultimately a very faintly coloured, or, as in the case of ciders, almost colourless filtrate is obtained. The extractive matters that then remain in solution give no precipitate with acetic acid and lead acetate in the presence of an excess of 80-85 per cent. alcohol. The process is as follows: 100 cc. of wine are evaporated on a water-bath to a few cubic centimeters volume, transferred to a flask, four or five cc. of twice normal sulphuric acid added and allowed to stand at the ordinary temperature for one hour. After this interval a mixture of 50 cc. of strong alcohol and 50 cc. of ether is gradually added during continuous shaking, and the liquid allowed to stand for from six to ten hours. In this time the matters insoluble in ether-alcohol will have well settled or subsided. The precipitate is filtered and washed with ether-alcohol, and to the filtrate 100 cc. of water is added, to prevent as far as possible the etherification of the acids present, and it is then distilled on the water bath to remove the greater part of the ether-alcohol, which is finally removed by distilling *in vacuo*. After the liquid free from alcohol has cooled to from 50 to 60°, the chlorine present is separated by addition of as small as possible an excess of a freshly prepared solution of silver sulphate. At this

temperature, in the presence of free sulphuric acid, only a slight reduction of silver takes place. After the precipitate of silver chloride has been filtered, the filtrate is neutralised with potassium carbonate and evaporated to small bulk. It is then treated exactly as described in the author's method for separating succinic, citric and tartaric acids from malic acid (*loc. cit.*). In the case of fruit wines containing no tartaric acid, it is only necessary to pass carbonic acid once through the filtrate obtained after the first treatment with barium hydrate, until it shows but a slight alkalinity. In analysing cider it is better to take not more than 50 cc. of the liquid, on account of the large quantity of malic acid contained in it.—H. S. P.

*Detection of the Higher Alcohols in Spirits of Wine.*  
Hardy. *Deutsch-Amerik. Apotheker-Zeit.* **13**, 73; *Zeits. Anal. Chem.* **32**, 477.

The spirits of wine is to be mixed with  $4\frac{1}{2}$  times its volume of a saturated solution of sodium chloride and  $\frac{1}{2}$  its volume of water, and is then several times shaken up with carbon bisulphide. The latter is then separated from the saline solution, and some concentrated sulphuric acid added to it. The carbon bisulphide and sulphuric acid are now separated and air is blown through the sulphuric acid to completely expel the carbon bisulphide, after which the sulphuric acid is mixed with an equal volume of glacial acetic acid and boiled for a quarter of an hour in conjunction with a reflux condenser. On now adding a volume of saturated salt solution equal to the original volume of spirits of wine taken, the acetic ethers of the butyl and amyl alcohol present separate out in oily drops. From the volume of these ethers collected and measured in a narrow graduated tube, the quantity of the originally present higher alcohols is found by multiplying the volume by 0.8.—H. S. P.

*Estimation of Succinic Acid formed in Fermentations.* A. Bau. *Archiv. f. Hygiene*, **14**, 225; *Zeits. Anal. Chem.* **32**, 482—486.

THE author has investigated the question, in what way the quantity of succinic acid formed in fermentation is affected by the conditions under which the fermentation is accomplished, and in order to do this he found it necessary to devise a suitable method for estimating succinic acid, especially in wine or other fermented liquids. He examined and found unsatisfactory the methods of Pasteur, Macagno, Kayser, and of Schmitt and Hiefe. As the result of his own experiments upon the solubility of succinic acid in various liquids and upon its behaviour with various reagents, he proposes the following method. 100 cc. of wine are evaporated to a syrup, repeatedly extracted on the water-bath with boiling alcohol, and each of the alcoholic extracts filtered after cooling. These extracts are mixed together and distilled, and the residue is dissolved in a little hot water and, if turbid after cooling, the solution is filtered. The clear filtrate is then treated with barium nitrate and with 3 to 4 times its volume of 90 per cent. alcohol and vigorously stirred. A precipitate containing the tartaric, malic and succinic acids forms, and after subsidence it is thrown on a filter and washed with 70 per cent. alcohol. It is now warmed for some time with a sufficient quantity of sodium carbonate solution, and filtered. The filtrate is neutralised with nitric acid, evaporated to a small bulk, and after neutralising with ammonia, it is saturated with a magnesia mixture containing magnesium nitrate, ammonium nitrate, and ammonia. After standing for from 3 to 4 hours, the precipitate due to tartaric acid is filtered off and the filtrate heated with potassium hydrate solution until all the ammonia has been expelled. The precipitate of magnesia is then filtered off, the filtrate exactly neutralised with nitric acid, diluted to from 100 to 150 cc. and silver nitrate solution (1:20) added which precipitates the succinic acid. The precipitate is collected on a tared filter, well washed, dried, and weighed. As a check it is burnt off in a porcelain crucible and the metallic silver remaining is weighed. The results calculated from the two weighings should agree.

Silver nitrate only precipitates tartaric acid from concentrated solutions and only precipitates malic acid from solutions containing more than 1 part in 800. In some cases (as when in the precipitations of the mixed acids with barium nitrate and alcohol, too much of the latter has been added and the precipitate has been allowed to stand too long for the purpose of subsiding before filtration) chlorine is present in the solution from which the silver succinate has to be separated, and when this is the case, 25 cc. of the solution must be evaporated to dryness, incinerated, and the chlorine determined in the aqueous solution of the ash, and the corresponding amount of silver chloride must then be subtracted from the weight of the precipitate of silver succinate.—H. S. P.

*A Study of the Methods of Estimating Glycerol.* E. Sohr. *Archiv. f. Hygiene*, **14**, 395; *Zeits. Anal. Chem.* **32**, 486—488.

THE methods of Diez, von Törning, Planchon, and the so-called "Reichs Methode," are particularly examined.

With regard to Diez's method (*Zeits. Anal. Chem.* **27**, 519; this Journal, 1888, 397, 696), the author finds two objections, viz., that the separated mixture of esters (consisting of glycerol tri and di-benzoate) which is obtained by treating the diluted solution of glycerol with benzoyl chloride and caustic soda solution cannot be washed free from benzoyl chloride, according to the originally prescribed procedure, because it is often a resinous or sticky mass which retains the benzoyl chloride; and, further, that the drying of the mixture of esters at 100° leads to error as it begins to decompose at this temperature. He proposes to overcome the first difficulty by washing the mixture of esters on the filter with water at 80° C. and a little caustic potash solution, until the smell of benzoyl chloride is gone, and finally to wash with water until the washings are quite neutral. In this way the mixture of esters becomes melted and then more readily is washed free from benzoyl chloride. Instead of drying and weighing the mixture of esters, he recommends saponifying it with half normal alcoholic solution of potash, using only a slight excess of the latter. After boiling a short time on the water-bath, the excess of potash is titrated with hydrochloric acid. He shows that substantially only the tribenzoate is formed, when the proportion of potash used attains almost exactly 3 molecules of potassium hydrate, 168 to 1 molecule of glycerol, 92.

Von Törning's method (*Zeits. Anal. Chem.* **28**, 363; this Journal, 1889, 124) he has modified to some slight extent in regard to the apparatus used. Instead of an air-bath of sheet iron, he uses a copper mantle packed with asbestos, which incloses the retort. An aperture is made in the cover to admit a thermometer. He prefers to use a retort without a tubulus, and when additions of water have to be made he allows the retort to cool, and after disconnecting the retort from the condenser adds the water by the neck. When using retorts with a tubulus and cork, he always found the cork became carbonated. In the distillate he estimates the glycerol by his modification of Diez's method, and obtains good results.

He also has modified Planchon's apparatus somewhat (*Zeits. Anal. Chem.* **28**, 356; this Journal, 1888, 779; 1889, 308, 480), chiefly with a view to preventing the water vapour passing over into the absorption apparatus. His arrangement is as follows:—The flask in which the glycerol is oxidised with potassium permanganate and sulphuric acid, is closed with a double-bored india-rubber cork, through one hole of which a tube reaching to the bottom of the flask passes, serving to allow of a current of air free from carbonic acid being drawn through the flask, whilst through the second hole of the cork is passed the condensation tube of a Liebig's condenser which is attached in an upwards inclined direction, so that the water vapour from the flask becoming condensed, flows back to the flask, whilst the carbonic acid evolved by the oxidation of the glycerol passes on to the drying and absorbing apparatus. This consists of first of all a U-tube in the bottom of which are placed a few pieces of calcium chloride, next a U-tube, one half filled with calcium chloride and the other half with pumice impregnated with copper

sulphate (which has been heated until white), after this a Liebig's potash apparatus containing 30 per cent. solution of potassium hydrate, which is followed by a small U-tube containing potassium hydrate, and finally a wash-bottle containing potassium hydrate solution which serves as a safety-flask preventing access of carbonic acid from the outside air. An intermediate flask is also introduced between this safety flask and the aspirator which is attached to the end of the train.

The operation is begun by slightly warming the liquid in the evolution flask; afterwards the heat is gradually increased until the evolution of carbon dioxide becomes small. The aspirator is then connected and a current of air is drawn through the apparatus. The results obtained and given by the author are very good.

The author then compares results he obtains in estimating glycerol in wine, mixtures of glycerol and sugar, &c., by the so-called "Reichs Methode" (*Zeits. Anal. Chem.* **23**, 392), and by von Töring's method, determining the glycerol in the distillate yielded by the latter process partly by Diez's process and partly by Planchon's, both modified by himself as above described. Confirming the results of other chemists, he finds that the glycerol separated by the "Reichs Methode" is far from pure, and that von Töring's method combined with Diez's gives by far the best results.

He recommends Planchon's method for estimating the amount of glycerol in aqueous solutions of glycerol, such as the "glycerine" of commerce, &c.—H. S. P.

*The Determination of Formic Acid.* A. Lieben. *Monatsh. Chem.* 1893, **14**, 746—754.

THE volumetric determination of formic acid by oxidation with potassium permanganate cannot be carried out in acid solutions, since the oxidation is too slow in the cold, whilst heating volatilises a portion of the formic acid. The author's results go to show however that accurate results may be obtained in a solution of the acid containing an excess of sodium carbonate, the oxidation proceeding according to the equation:—

The accuracy of the results are not influenced by the quantity of sodium carbonate added. The titration is carried out by a permanganate solution, the strength of which has been fixed by means of iron. It is advantageous to warm the solution on the water-bath during the titration, as this hastens the reaction and causes the precipitated manganese dioxide to separate more readily, thus allowing the coloration, due to an excess of permanganate, to be more distinctly seen in the supernatant liquid. It is necessary to allow the solution to stand a little after the titration is completed to make sure that an excess of permanganate has been added. A number of analytical data show the accuracy of the method, which holds for salts of formic acid as well as for the free acid, but which is inapplicable in presence of other oxidisable substances.

The author also gives details of experiments on the value of Seala's method (*Gazzetta Chim.* 1890, **20**, 393) for the determination of formic acid by heating a neutralised solution of the acid with mercuric chloride, and weighing the mercurous chloride formed after drying it at 100° C. These experiments show that the process is only approximately accurate (within 1 to 2 per cent. on the formic acid present) if a large excess of mercuric chloride be employed and the mixture be heated on the water bath for at least 6 to 8 hours, instead of 2 hours, as recommended by Seala. Otherwise the results are much too low. The quantity of mercuric chloride added should be 50 times the weight of the formic acid, or 4 times the theoretical quantity required, according to the equation:—

The addition of potassium butyrate or the heating of the mixture in a sealed tube to 102° C. does not increase the accuracy of the method.—C. A. K.

*The Quantitative Estimation of Acetone and Salicylic Acid in "Sal acetol."* H. Eckenroth and K. Kock. *Pharm. Zeit.* 1893, **38**, 593.

"SAL ACETOL" is the product of the combination to an ester of salicylic acid and acetone, its formula being  $\text{OHC}_6\text{H}_4\text{COOCH}_3\text{COCH}_3$ . It is saponified by caustic alkali with formation of acetone and alkaline salicylate. To examine it, 0.5 grm. is dissolved in water and titrated with decinormal potash, using phenolphthalein as an indicator, the flask being warmed; 26 cc. of alkali should be neutralised.—F. H. L.

*The Quantitative Estimation of Acetone and Salicylic Acid in "Sal acetol."* H. Helbing and F. W. Passmore. *Pharm. Zeit.* 1893, **38**, 621. Compare preceding abstract.

THE authors state that the preceding account of the decomposition of "sal acetol" on saponification is incorrect. The products are a salicylate, and acetone-alcohol—

Sal acetol is readily soluble in weak alkalis, and the colourless solution contains the hydrolysed products which reduce Fehling's solution in the cold. By gentle warming the alkaline liquid becomes brown in colour, and the characteristic smell caused by the action of alkalis on sugar is produced. This reaction is due neither to acetone nor salicylic acid, and as they do not reduce Fehling's liquid, these tests show the presence of the acetone-alcohol. Sal acetol should contain 71.16 per cent. of salicylic acid, and it should be examined for chlorine compounds, which may be introduced during the manufacture.—F. H. L.

*The Analytical Determination of Probably "Available" Mineral Plant Food in Soils.* Bernard Dyer. *Proc. Chem. Soc.* 1894, [134], 36.

PRINCIPALLY refers to experiments made by the author in endeavouring to decide what was the most useful solvent for extracting "available" (as distinguished from "total") mineral constituents of plant food from soil.

These experiments led him to seek to determine the average acidity of the root sap which plants have at their disposal as a natural solvent for such constituents. Determinations involved in the examination of about 100 plants, made in order to arrive at this, are recorded in detail.

As these determinations appeared to indicate the suitability as an analytical soil solvent of a 1 per cent. solution of citric acid—the same solution that, on grounds quite differently approached, had been suggested by Tollens and Stutzer as an agent for like purposes in testing manures—the author decided to try the effect of the solution on soils of known history and recorded fertility.

For the purposes of this trial, 22 separate plots of the experimental barley field at Rothamsted were sampled, with the kind permission and assistance of Sir John Lawes, and Sir J. H. Gilbert, and the samples were all subjected to separate investigation. A detailed account of this work is given, and its results discussed, the general conclusion being that the use of the suggested solution does give valuable indications of comparative ("mineral") soil fertility such as are not obtained in ordinary soil analysis.

Appended to the account of the work on soils is an account of some experiments on phosphatic manurial materials, comparing the solvent action of alkaline ammonium citrate and dilute citric acid, the result of which is to confirm the views of Tollens and Stutzer, to the effect that, although ammonium citrate may suffice to dissolve "reverted" or "retrograde" phosphate, it does not suffice to indicate "available" phosphate, and that its use ought to be superseded by that of a weak solution of citric acid.

# ANALYTICAL AND SCIENTIFIC NOTES.

*A Coal containing Vanadium.* A. Mourlot. *Comptes rend.* 1893, **117**, 546—548.

THE analysis of coal containing vanadium and which was obtained from Mendoza in the Argentine Republic has been given by Kyle (*Chem. News*, 1892). The author has examined a similar coal and found that it contains 0.21 per cent. calculated on the coal, and 38.5 per cent. calculated on the ash.—A. K. M.

*The Physiological action of Tellurous Acid.* T. Bokorny. *Chem. Zeit.* **17**, 1598—1599.

THE result of experiments on the toxic power of tellurous acid with respect to lower forms of life (*Spirogyres Zygnema*, *Diatomaceae* and *Infusoria*) is to show that the action is but faintly marked, or not at all observable. Selenious acid is somewhat more active, especially in solutions not neutralised; whilst sulphurous acid is still more energetic, especially when free.—C. R. A. W.

*Sodium Salt of Perchromic Acid.* J. Häussermann. *J. Prakt. Chem.* **48**, 70—72.

WHEN sodium peroxide is added to chromic hydroxide stirred up with water to a thin paste and kept cooled below 20° C., a violent reaction takes place, the hydroxide dissolving with formation of a yellowish brown liquid. On standing for some time in a cool place the solution deposits shining brownish-red crystals with the formula—

The substance may be heated with alkaline solutions without decomposition. Sulphuric acid at once gives the characteristic colour of perchromic acid, and hot water decomposes the compound according to the equation—

—J. W.

## New Books.

THE ALCHEMICAL ESSENCE AND THE CHEMICAL ELEMENT. An Episode in the Quest of the Unchanging. By M. M. PATRISON MURK. London: Longmans, Green, and Co. New York: 15, East 16th Street. 1894. 4s. 6d.

OCTAVO volume, bound in cloth, containing 94 pages of subject-matter. In these pages is portrayed the development of alchemy, and it is shown that all that alchemy did or could do, was to spread "a wondrous veil" over nature. This development is traced up to the period when chemistry commenced "hesitatingly to withdraw" that veil.

DIE SELBSTENTZÜNDUNG VON SCHIFFSLADUNGEN, BAUMWOLLE UND ANDEREN FASERSTOFFEN, STEINKOHLEN, HEUHAUFEN, TARAK, &c., SO WIE DEREN VERHÜTUNG. Von Dr. L. HÄPKE. Zweite, erweiterte Auflage, mit 10 Holzschnitten. Bremen: C. Ed. Müller's Verlagsbuchhandlung. 1893. London: H. Grevel and Co., 33, King Street, Covent Garden. 2 40 M., or about 2s. 5d.

A MONOGRAPH on the subject of Spontaneous Combustion. The work is stoutly bound in cloth, is of 8vo. size, and contains 105 pages. The subject matter is subdivided as follows:—Introduction. Origin and Causes of Spontaneous Combustion. I. Coals. II. Coal-dust, Briquettes, Soot, and Bone-black. III. Cotton. IV. Wool, Silk, Flax, Hemp, and Jute. V. Hay and Grain. VI. Various Substances. The work is illustrated by 10 wood-engravings.

UNIVERSAL EXPOSITION AT PARIS, 1889. REPORT ON CHEMICAL AND PHARMACEUTICAL PRODUCTS. By SPENCER R. NEWBERRY. Washington: Government Printing Office, 1893.

THE following branches are reported upon, the report covering some 140 pages:—I. Sulphur and its Derivatives. II. Sulphuric Acid. III. Alkali Manufacture. IV. General Chemical Products. V. Explosives. VI. Gelatin, Glue, Bone-black, and Phosphorus. VII. Soaps, Glycerin, and Stearin. VIII. India-rubber and Gutta Percha. IX. Pigments, Paints, and Varnishes. X. Pharmaceutical Products. XI. Products of Petroleum Distillation. XII. Products of Forestry. XIII. Agricultural Products not used as Food. XIV. Chemical Methods of Bleaching and Dyeing. XV. Leather and Skins. XVI. Fertilisers of Organic or Mineral Origin.

PRINCIPLES AND PRACTICE OF AGRICULTURAL ANALYSIS. A Manual for the Examination of Soils, Fertilisers, and Agricultural Products. For the Use of Analysts, Teachers and Students of Agricultural Chemistry. By HARVEY W. WILLEY, Chemist of the U.S. Department of Agriculture. Vol. I. No. 1. 25 cents. Easton, Pa., Chemical Publishing Co.

THIS is Part 1, of a series of monthly issues to follow, of the work under consideration, and is mainly confined, in the course of its 48 pages, to general definitions, and a descriptive account of the rocks, the micro-structure of which is illustrated in a series of admirably executed engravings from photographs.

## Trade Report.

### TARIFF CHANGES AND CUSTOMS REGULATIONS.

PROPOSED NEW COMMERCIAL TREATY BETWEEN RUSSIA AND GERMANY.

*A—Russian Concessions to Germany.*

[Note.—Poud = 36 lbs. avoirdupois; Funt = 0.902 lbs. avoirdupois; Rouble = 3s. 2d.]

Tariff Classification.	Rates proposed to be levied under Russo-German Treaty.	Rates at present leviable under Russian Minimum Tariff.
Potato fecule .....	Poud Rbls. cop. 0.60	Poud Rbls. cop. 1.40
Starch of all kinds; dextrine. „	1.15 „	1.40
[Starch and dextrine imported in boxes, packets, or other small receptacles „	Poud gross 1.50	Poud gross 1.75
Cement of all kinds (natural or artificial Portland, Roman, cement made from scoria, and all others); bricks, slabs, and pipes of cement.	Poud 0.08	Poud 0.09
Baryta; sulphate of baryta ( <i>blanc fixe</i> ) and carbonate of baryta, artificial.	„ 0.80 „	1.00
Salts of chromic acid soluble in water; e.g., bichromate of potash, neutral chromate of potash, chromate of soda.	„ 2.15 „	2.65
Tannic acid (tannin) .....	„ 5.00 „	6.00
Blue coppers, (except anhydrous coppers, Salzbürg coppers (a mixture of sulphates of iron and copper), white coppers, or sulphate of zinc; chloride of zinc.	„ 0.80 „	1.00
Tartar emetic .....	„ 3.00 „	4.00

Colours with base of copper (except verdigris) or of arsenic.	" 3'00	" 4'00
Verdigris (basic acetate of copper).	" 3'50	" 4'00
Painting substances (pigments) prepared with products from the distillation of coal tar; alizarine, extract of madder, lac of madder or alizarine; cochineal carmine, carmine lac; indigo; turmeric and saffron extract in a dry state.	" 14'00	" 17'00
Colouring substances mixed with non-colouring materials such as clay and oil pay duty at the rate of 3 roubles per poud when the colouring substance does not exceed 10 per cent. of the total weight of the mixture.		
Fine colours for miniatures in china or porcelain cups or saucers, in tubes, or in tin capsules; Indian ink, liquid, in flasks.	" 5'00	" 5'00

## NORWAY.

## Tariff Changes.

Mr. A. S. MacGregor, Acting British Consul-General at Christiania, in a report to the Foreign Office, dated the 9th February, encloses the following list of alterations made by the Storting, on the 6th February, and coming immediately into operation in the customs duty and excise on spirits and malt:—

On spirits in bottle or jars, without any respect to strength, kr. 1.90 (2s. 1d.) per litre (formerly kr. 1.6 = 1s. 9d.)

On spirits in receptacles other than the above mentioned, kr. 2.03 (2s. 3d.) per litre of 100 per cent. alcoholic strength (formerly kr. 1.71 = 1s. 10½d.)

On spirits containing substances affecting the alcoholic strength, kr. 2.55 (2s. 10d.) per kilos, tare; as regards casks, 15 per cent. (formerly kr. 2.15 = 2s. 5d.)

On ether and naphtha, kr. 3.60 (4s.) per kilo. (formerly kr. 3.10 = 3s. 5½d.)

On vinegar-ether ("Eddike æter,") kr. 1.35 (1s. 6d.) per kilos. (formerly kr. 1.15 = 1s. 3½d.)

On "Ether spirituosus" and other ethers containing spirits, kr. 2.55 (2s. 10d.) per kilo. (formerly kr. 2.15 = 2s. 4½d.)

On perfumed waters and aromatic vinegar (including packing), kr. 2.35 (2s. 7½d.) per kilos. (formerly kr. 2.00 = 2s. 2½d.)

On varnishes and polish, kr. 2.35 (2s. 7½d.) per kilos, tare; metal packing 8 per cent. (formerly kr. 2.00 = 2s. 2½d.)

On methylated spirit—Spirit, 10 öre (1½d.) per litre; varnish, 10 öre (1½d.) per litre.

## FINLAND.

## The Duty on Sulphate of Potash and Soda.

Mr. J. Michell, Her Majesty's Consul at St. Petersburg, in a report to the Foreign Office, dated the 20th February,

states that, according to information supplied by Mr. C. J. Cooke, British Vice-Consul at Helsingfors, the Imperial Senate of Finland has established a duty of 1 mark 20 penni Finnish currency per 100 kilos, of sulphate of potash and soda (natrium sulphuric) imported into the Grand-Duchy, the above duty being leviable from the 16th February.

## EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

## NEW BELGIAN REGULATIONS AFFECTING THE ADULTERATION OF BEER.

Sir F. R. Plunkett, Her Majesty's Minister at Brussels, in a despatch to the Foreign Office, dated the 9th February, encloses copy of a royal decree published in the *Moniteur Belge* establishing new regulations for preventing the adulteration of beer, and for ensuring, as far as possible, that the beer should reach the consumer in good condition. The following is a translation of these regulations:—

Art. 1. It is strictly prohibited to use in the manufacture and preparation of beers products containing matters injurious to health, as also to sell, expose for sale, detain or transport for sale beers containing these matters, or beers otherwise adulterated.

For the application of the present regulations, such antiseptics as salicylic acid, sulphuric acid, or their saline preparations are considered as injurious to health. The presence of sulphuric acid is, however, permissible in beers when the proportion does not exceed 14 mgrms. per litre, probably originating in a careful disinfection of the casks.

Art. 2. Casks, bottles, or other receptacles, in which beers are contained for the wholesale trade, or in demi-johns, must bear in distinct characters the name and description, as well as the address of the maker or merchant.

Every factory or trade-mark, regularly deposited, will be sufficient for the purposes of the above regulations.

Art. 3. Taps, pipes, pumps, carbonic acid apparatus, &c., used for the serving of the beer must be kept perfectly clean.

The air admitted to the beers in casks for sale must come from a place free from any cause of contamination and well ventilated if possible from outside the houses.

Art. 4. It is prohibited to sell, expose for sale, detain or transport for sale *stortbier*, collected in the shops at the bottoms of glasses or on the tables and counters, unless these liquids are denaturalised in such a way that they cannot be utilised as beer, nor serve for mixing with beers, nor be employed in the manufacture of vinegar.

Art. 5. Infractions of the preceding regulations will be met with the penalties provided in the law of the 4th August 1890, without prejudice to the application of the penalties provided by the Penal Code.

## INTERNATIONAL BOOK AND PAPER INDUSTRIES EXHIBITION AT PARIS.

According to an announcement in the *Bulletin du Musée Commercial* for the 10th February, an international book and paper exhibition will be open in Paris at the Palais de l'Industrie from the 23rd July to the 23rd November next.

## THE FOREIGN TRADE OF GERMANY IN 1893.

The following is a comparative statement of the values of each class of imports into Germany in 1893 and 1892, as enumerated in the official returns:—

Category.	1893.	1892.
	Marks.	Marks.
Refuse (rags, &c.)	62,488,000	47,324,000
Lead and lead wares	5,717,000	4,322,000
Drugs and dyestuffs	243,445,000	235,433,000
Earths, ores, precious metals, and asbestos	298,296,000	317,752,000

THE FOREIGN TRADE OF GERMANY IN 1893—*cont.*

Category.	1893.	1892.
	Marks.	Marks.
Glass and glass wares.....	8,165,000	8,201,000
Hides and skins.....	117,543,000	126,620,000
Caoutchouc, gutta percha, and wares thereof.....	37,135,000	33,165,000
Copper and copper wares.....	56,931,000	52,198,000
Leather and leather wares.....	17,176,000	13,998,000
Candles.....	131,000	96,000
Oils, excluding petroleum and fatty substances.	158,775,000	175,067,000
Paper and paper wares.....	12,239,000	10,816,000
Petroleum.....	76,926,000	73,508,000
Soap and perfumery.....	2,331,000	2,287,000
Stone and stoneware.....	38,505,000	39,858,000
Coal, lignite, &c.....	98,737,000	95,101,000
Straw and bast goods.....	6,243,000	5,722,000
Tar, pitch, resin, and asphalt.....	30,856,000	27,927,000
Earthenware.....	5,772,000	5,343,000
Floorecloth, &c.....	992,000	1,160,000
Zinc and zinc wares.....	6,035,000	5,874,000
Tin and tin wares.....	20,066,000	17,633,000

The following statement shows the values of each category of exports from Germany in 1893 and 1892 :—

Category.	1893.	1892.
	Marks.	Marks.
Refuse (rags, &c.).....	12,558,000	10,311,000
Lead and lead wares.....	9,508,000	9,367,000
Drugs and dyestuffs.....	277,588,000	262,011,000
Earths, ores, precious metals, and asbestos	232,410,000	237,077,000
Glass and glass wares.....	43,552,000	37,752,000
Hides and skins.....	61,956,000	62,401,000
Caoutchouc, gutta percha, and wares thereof.....	28,868,000	26,953,000
Copper and copper wares.....	61,277,000	56,226,000
Leather and leather wares.....	117,768,000	110,116,000
Candles.....	799,000	800,000
Oils, excluding petroleum, and fatty substances.	30,615,000	23,518,000
Paper and paper wares.....	95,843,000	91,639,000
Petroleum.....	673,000	575,000
Soap and perfumery.....	10,338,000	9,284,000
Stone and stoneware.....	22,913,000	25,396,000
Coal, lignite, &c.....	142,720,000	131,212,000
Straw and bast goods.....	3,940,000	4,027,000
Tar, pitch, resin, and asphalt.....	6,828,000	7,585,000
Earthenware.....	37,831,000	35,205,000
Floorecloth, &c.....	1,103,000	928,000
Zinc and zinc wares.....	37,581,000	32,929,000
Tin and tin wares.....	4,669,000	4,157,000

## CHEMICALS AND DYES ON FREE LIST IN THE NETHERLANDS.

The United States Minister, under date of January 9, 1894, informs the Department that the Netherlands Govern-

ment has granted exemption from Customs duties to chemicals, dyes, and other material of a similar nature used as auxiliaries in operations in factories or trades, and from spirits, excise, and Customs duties to chemicals imported to that country destined for use in institutions for the instruction of natural sciences.

## GENERAL TRADE NOTES.

## THE SOLIDIFICATION OF PETROLEUM.

The *Moniteur Officiel du Commerce* for the 8th February gives the following as the formula of M. Maestraci, of the French navy, for obtaining briquettes of petroleum similar to those of coal.

With a litre of petroleum there is mixed 150 grams of triturated soap, 10 per cent. of resin, and 333 grams of caustic soda. This mixture is heated, care being taken to stir it; when solidification commences, which takes place at the end of about 10 minutes, observation is made as to the progress of the operation. If the mixture shows a tendency to overflow, some drops of soda are placed in the receptacle. The stirring is continued until solidification is complete.

The operation being finished, the material is poured out into moulds so as to make the briquettes, which are then placed from 10 to 15 minutes in a stove. All that remains is to let them cool; these briquettes can be used a few hours after manufacture.

To the three elements constituting the mixture, M. Maestraci recommends further the addition of 20 per cent. of wood shavings, and 20 per cent. of clay or sand which makes them firmer and more lasting.

Some trials in heating have recently been made at Marseilles on several tug-boats with these briquettes. An equal weight supplied three times the heat of ordinary coal briquettes, and there is no waste.

It is hoped with very simple modifications in the fire-places to arrive at still better results, the suppression of smoke and an increased production of heat, so that 1 kilog. of solidified petroleum will be equivalent to 4 kilogs. of coal.

## THE USE OF ALUMINIUM FOR LITHOGRAPHY.

The New York *Iron Age* for the 18th January publishes the following :—

Aluminium has been found adaptable to many purposes, and constant announcements are made of some new use to which the metal has been put. The latest is in lithography, in which process it is claimed to possess many advantages over the stone now used, while fulfilling all the requisite conditions. The only stone used for lithographing is found in Bavaria, and as the supply is diminishing its cost is increasing. Moreover, it is very brittle, and being rigid, can only be used on flat surfaces. Under a recently patented process, we learn that aluminium plates, weighing from 2 to 10 lb. and costing from 5 dols. to 10 dols., do the work equally well, and that, being flexible, the plates can be moulded into forms for cylinder presses. Aluminium plates are also coming into use in engraving in place of steel.

## RUSSIAN SUGAR PRODUCTION.

According to a recent report of the French Ambassador at St. Petersburg, extracts from which are given in the *Moniteur Officiel du Commerce* for the 25th January, the quantity of moist-sugar submitted for refining during the 1892-3 sugar season in Russia was 1.7 per cent. higher than in 1891-2, the total production of refined sugar having been 15,558,000 pounds (pound = 36 lbs. avoirdupois), or 4.6 per cent. more than in the preceding season. The quantity of sugar placed on the market by the refineries represented 15,077,000 pounds, as compared with 15,612,000 pounds in 1891-2, or a decrease of 535,000 pounds.

A new refinery commenced working in 1893 in the government of Livonia. The provinces of Kiew, Kharkow, and Podolia have supplied the best results, while on the other hand those of the provinces of Kherson and Moscow have been less satisfactory.

It is estimated that the beet crop in Russia in 1893 yielded 55 per cent. more than in 1892 (34,000,000 berkovets = berkovet = 360 lbs. avoirdupois—as compared with 21,800,000 berkovets in 1892). The average production per deciatine (1 deciatine = 2·7 acres) in 1893 was 111·32 berkovets against 81·15 in 1892. Although the crop was satisfactory as regards quantity, such was not the case as regards quality, which left much to be desired. On the average the density of the beets harvested in 1893 was only 17·52 in place of 17·92 in 1892; again the saccharin richness represented only 14·40 in place of 14·94 for 1892. It is only in the Polish provinces that the beets are of a superior quality to those harvested in 1892.

#### GERMAN SUGAR-BEET RETURNS.

The United States Consul at Magdeburg, in a recent report to his government, deals with the official statistics of the German beet-sugar industry and states as follows:—

The year 1892–93 has been of special importance to the sugar growers, as the system of taxation was changed by law of May 31st, 1891, to go into effect August 1st, 1892. Under the old law, beets were taxed 80 pfennigs per 100 kilogrammes, and an additional tax of 12 marks was levied on every 100 kilogrammes of sugar for domestic consumption. This tax of 80 pfennigs on the beets was refunded on exported sugars by means of a premium. The new law dropped the beet tax of 80 pfennigs entirely and substituted a tax of 18 marks per 100 kilogrammes on sugars for domestic consumption. The sugars which are exported are, as heretofore, exempted from this tax, but the export premium, which amounted under the old law to 8·50 marks per 100 kilogrammes, is reduced as follows:—

Description.	August 1st, 1892, to July 31st, 1895.	August 1st, 1895, to July 31st, 1897.
	Marks. 1·25	Marks. 1·00
On raw sugar of at least 90 per cent. and refined sugar of from 90 to 98 per cent. purity.	2·00	1·75
On candies and sugars in white, full, hard leaves, blocks, sticks, and crystals, and other sugars of at least 90 per cent. purity.	1·65	1·40
On all other hard sugars		

After July 31st, 1897, all bounties are to be discontinued. It is stated, however, in the press that the sugar growers and refiners are putting out feelers already to have this premium system continued after July 31st, 1897, claiming that they would be at too great a disadvantage with other countries, principally France and Belgium, if the premium was dropped entirely.

By the same law the duty on imported sugars was raised from 30 marks to 36 marks, excepting on such imported sugars as enter again into the manufacture here. Such sugars are credited with the consumption tax of 18 marks, thus paying only a net duty of 18 marks per 100 kilogrammes.

#### FRENCH MARGARINE PRODUCTION.

The *Monde Economique* for the 3rd February states that eight Bordeaux houses, including the manufacturers of seed oils, merchants, and ships' captains, have petitioned the members of the Chamber of Deputies in favour of margarine and against the proposals made to suppress it. It is, the petitioners state, perfectly wholesome, and by reason of its low price, being in fact from 30 to 40 per cent. less than butter, it can be purchased by the poorer classes who cannot afford butter. It is of importance to the Bordeaux trade, which imports ground-nuts from Senegambia for the works,

making a superior oil, these nuts being also used in other countries to give to the margarine-butter a nutty taste and elasticity; it is of interest also to agriculture, the milk and fat being used. Adulteration, it is said, is not practised by the large factories nor in the warehouses, but by certain firms who mix calf fat or similar substances with their butter in order to deceive purchasers.

#### INDIGO CULTIVATION IN THE PUNJAB.

It appears that an unusually large crop of indigo was obtained last year in the Punjab. The *Calcutta Englishman* in its issue of the 24th January states that the area cultivated is estimated at over 110,000 acres, an increase of 70 per cent. over the previous year, and the amount of dye obtained at 817,000 seers, an increase of about 60 per cent. Statistics of the Punjab indigo crop are available only for the past three years; and we have therefore no exact information concerning the normal out-turn. The area under indigo this year is unusually large, and the out-turn in dye is estimated at 15 annas.

#### THE BASIC STEEL PRODUCT IN 1893.

The growth of the production of steel by the Thomas-Gilchrist or basic process is shown by the returns just received for the *Mineral Industry*, giving the output for 1893 under the patents covering that process in the different iron-making countries of the world. The figures are in metric tons, and we compare them here with those for 1892:—

#### Total Production of Thomas-Gilchrist (Basic) Steel.

	1892.	1893.
Germany and Luxemburg.....	2,013,184	2,308,937
England.....	406,839	363,800
France.....	287,529	332,407
Austria-Hungary.....	288,522	320,063
United States.....	91,729	262,408
Russia.....	58,661	
Belgium.....	56,274	
Total.....	3,202,640	3,587,615

This shows an increase of 384,975 tons, or 10·7 per cent. in a year which has not been a favourable one for the industry, since it has been in almost all countries one in which the iron and steel industries have shown a temporary decline, or have at least been stationary. The total production of steel by this process since its first introduction is given in the *Mineral Industry*, Vol. 2, now in press.

The growth has been constant and marked, except in the especially unfavourable year of 1888. Germany continues to be the country where the process is most in favour, its especial adaptation to the phosphoric ores of some of the leading iron districts having given it a standing there and brought it into favour at an early date. In England there was a decrease of some 10·5 per cent. in the output, a contrast to the showing in all the other European countries.

The figures for the United States in 1893 are as yet only estimated. The increased use of basic steel in this country in the future is probable.

A feature of considerable economic importance in this process is the large proportion—about 36 per cent.—of phosphate of lime contained in the slag. Last year a production of some 863,000 tons of this slag was reported, and nearly all of that made at the European works was ground and sold for use as a fertiliser, forming a considerable item in the profits of those works.—*Engineering and Mining Journal*.

## UNITED STATES EXPORTS OF PARAFFIN WAX.

There is no article produced in the United States, nor even refined petroleum, which shows such an enormous increase in the amount exported as does paraffin wax. This article, which is of comparatively recent introduction, has reached an important place in the exports which was not even dreamed of 10 years ago. Indeed, the production at that time did not reach one-half of the amount exported during the last calendar year, when the total exports amounted to over 99,000,000 pounds. The rapid growth of the consumption of this article is due mainly to the fact that new uses have been found for the material, chief among which is its employment in the electrical industry. The exports of nearly all the products of petroleum have shown remarkable increase during the past few years, but even those of illuminating oil bear no comparison with the enormous expansion in the demand for paraffin wax. This is probably due to the fact that there is practically no competition, the Russian petroleum producing no wax, and the only other source being the Scotch shale wax, or paraffin scale, as it is known commercially, but production of which is limited, and does not cut much of a figure even in the requirements for home consumption, and it is not suitable for the more important uses to which paraffin wax is applied. To show the steady growth of the United States foreign trade in this product we append the following table, giving the amounts exported during each of the past 10 fiscal years. It will be seen from this table, taken from the official reports of the Bureau of Statistics at Washington, that the increase in the shipments has been to the United Kingdom, although the requirements of Germany show some increase. The amounts given are in pounds:—

Year.	To United Kingdom.	To Germany.	Total.
1884	16,230,251	771,092	17,001,343
1885	21,826,882	2,202,221	24,029,103
1886	22,798,003	1,402,427	24,200,430
1887	29,130,847	2,205,530	31,336,377
1888	33,815,143	1,576,354	35,391,497
1889	29,424,089	3,751,830	33,175,919
1890	42,343,246	4,823,073	47,166,319
1891	53,562,105	3,673,045	57,235,150
1892	54,816,457	6,491,864	61,308,321
1893	63,404,093	4,862,210	68,266,303
Total, 10 years ..	378,351,716	31,768,676	410,120,392

It appears that the increase in exports is still going on at the same ratio, as is evidenced by the large shipments during the last half of 1893. While the total exports during the fiscal year (ended June 30, 1893) amounted to 82,675,140 pounds, those during the 12 calendar months reached the enormous total of 99,061,034 pounds.—*Oil, Paint, and Drug Reporter*.

## IMPERIAL INSTITUTE RESEARCH COMMITTEE.

A committee of advice has been appointed in connection with the Scientific and practical Research Department of the Imperial Institute, and the members have adopted a scheme of action which it is hoped will result in making the public acquainted with the resources of various countries, to enable men connected with commerce and industry to compare the products of particular classes furnished by the several countries, and also to direct the attention of those practically interested in them to new or little-known natural products and to furnish trustworthy information as to their nature, properties, and value. The following are the members of the committee of advice and the subjects with which they will deal:—Professor Armstrong, F.R.S., Dr. W. H. Perkin, F.R.S., and Professor Meldola, F.R.S. (dyes,

tanning materials, and organic products); Dr. Hugo Müller, F.R.S. (mineralogy, botany, and fibres); Mr. C. F. Cross (fibres); Professor Dunstan, F.R.S. (pharmaceutical products and drugs); Mr. David Howard (alkaloids and drugs); Professor A. H. Church, F.R.S. (agriculture); Mr. Boyerton Redwood (petroleum and oils); Professor Fisher's-Auster, F.R.S. (metallurgy, fuel, and oils); Mr. Bennett Brough (metallurgy, mining, and minerals); Professor W. C. Unwin, F.R.S. (structural materials); Professor Hummel (dyes and tans); Professor W. A. Tilden, F.R.S. (gums and resins); Mr. W. H. Dering (oils, waxes, and fats); Mr. H. A. Miers (mineralogy); and Mr. Horace T. Brown, F.R.S. (food-grains). Sir F. Abel, F.R.S., is director, and Mr. Theodore Cooke, L.D., is secretary of the committee.—*Chemist and Druggist*.

## BOARD OF TRADE RETURNS

## SUMMARY OF IMPORTS.

Articles.	Month ending 28th February	
	1893.	1894.
	£	£
Metals.....	1,682,538	1,529,112
Chemicals and dyestuffs.....	751,160	721,477
Oils.....	615,811	509,931
Raw materials for non-textile industries.	2,093,116	2,438,774
Total value of all imports....	24,759,610	33,981,085

## SUMMARY OF EXPORTS.

Articles.	Month ending 28th February	
	1893.	1894.
	£	£
Metals (other than machinery) ....	2,301,823	2,117,208
Chemicals and medicines .....	735,736	646,158
Miscellaneous articles.....	2,256,704	2,032,185
Total value of all exports.....	17,093,369	17,679,149

## IMPORTS OF OILS FOR MONTH ENDING 28TH FEBRUARY.

Articles.	Quantities.		Values.

## Monthly Patent List.

\* The dates given are the dates of the Official Journals, in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

### L—GENERAL PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

3414. A. J. Boulé.—From P. de Molle et A. Willbaux, Belgium. Improvements in or relating to the filtration and purification of liquids, and apparatus therefor. February 17.

3665. H. Evers-Swindell. Improved manufacture of gas-retorts also applicable to other tubular objects of fire-clay or earthenware, and apparatus therefor. February 20.

3702. W. Charley. Improvements in machinery for the compression of air or other elastic fluids. February 21.

3792. S. H. Sparkes. Improvement in hydro-extractors. February 22.

3799. W. Under and J. Willoughby. Improvements in the method of and apparatus for controlling the supply of air to furnaces. February 22.

3805. J. W. Brown. Float for determining specific gravity and consistency of boiling tar, asphalt, bitumen, and other liquids. February 22.

3887. W. A. Kirkham. Improvements in or appertaining to plant for evaporating brine. February 24.

4069. O. Hamilton. An improved heating apparatus more particularly applicable to chemical processes. February 26.

4094. S. C. Hauberg. Improvements in centrifugal liquid separators. Complete Specification. February 26.

4098. H. H. Lake.—From the Actien-Gesellschaft für Kohlenäure-Industrie, Germany. An improved cap for cylinders or receptacles for containing liquid or gas under pressure. February 26.

4350. A. Normandy. Improvements in apparatus for evaporating and condensing water. March 1.

4549. W. Smethurst and The Smokeless Heat and Light Syndicate, Ltd. Improvements in the process of and apparatus for evaporating liquids. March 3.

4622. B. Andrew. See Class XII.

4700. L. B. Burnett. Apparatus capable of ready application to ordinary gas burners to convert them into Bunsen burners. March 6.

4895. H. Digne. An apparatus for melting tallow and analogous products for the desiccation of fruits, and for other operations requiring an equal and regular temperature comprised between 20° and 200° C. March 8.

5119. D. Drummond. Improvements in apparatus for expressing sap or juice from fibrous canes and other materials. March 12.

5187. C. Long and W. H. Borkitt. An improvement in acid raisers of steam-jet pumps for the raising of acids, alkalis, and other liquids. March 13.

5262. W. Henneberg. Improvements in apparatus for condensing vapours and heating or vaporising liquids respectively. Complete Specification. March 13.

5568. C. E. Miles. Improved means for and method of condensing vapour and for producing a vacuum in pans or like vessels used for evaporating or concentrating liquids. March 16.

5569. E. Edwards.—From F. P. Hofmeister, Germany. Improvements in apparatus for effecting the absorption of gases by liquids. March 16.

5613. T. Drost. An improved process for saturating or mixing solid substances with liquids. March 17.

## COMPLETE SPECIFICATIONS ACCEPTED.\*

1893.

3170. J. A. Morrell and J. Fromberz. Improvements in apparatus applicable for evaporating liquids or saccharine solutions. February 21.

4245. A. Shields. Improvements connected with refrigerating apparatus. February 28.

7525. J. Drummond. Improvements in apparatus for filtering liquids or for separating liquids from or drying crystallised or other granular matters. February 21.

7912. T. R. Murray. Improvements in pumps for pumping or compressing gases or vapours. February 28.

8125. W. H. Webb. Improvements in or connected with apparatus for cooling liquids. February 28.

9808. N. Yagn. Improvements in apparatus for sterilising water. March 7.

16,663. G. Morris and W. Edney. See Class XVII. March 14.

17,737. F. S. Cripps. Improvements in valves for tar, ammoniacal liquor, and other liquids. March 21.

24,106. W. P. Thompson.—From H. L. Fuge. Improvements in pressure regulators or reducers for gases, liquids, or the like. February 21.

21,526. H. Reiser. Process and apparatus for cleansing filtering material. March 7.

1894.

70. G. Frere and M. Meslans. Improvements in the method of and apparatus for determining the density of gases. March 7.

## II.—FUEL, GAS, AND LIGHT.

## APPLICATIONS.

5018. A. Farinetti. An automatic apparatus to produce gas for the purpose of light connected therewith. February 12.

3078. J. Jameson. An appliance for increasing, or increasing and regulating, the pressure of illuminating gas in houses, factories, or shops. February 13.

3223. W. Donaldson. See Class XI.

3395. W. R. Herring. Improvements in and in apparatus for manufacturing oil-gas. February 16.

3420. A. A. Routledge and W. Usher. An improved carburetter, for saving gas and increasing its illuminating power. February 17.

3558. F. W. Golby.—From H. Leffler, Germany. Improvements relating to the purification of combustion gases and the utilisation of the heat contained therein. February 19.

3571. F. Ilavati and F. Slacký. See Class VII.

3771. W. H. White. An improved composition for fire-lighters. February 21.

3794. R. C. Wilford. Improvements in apparatus for producing and regulating a combustible mixture of petroleum and atmospheric air for the purpose of operating explosion engines. February 22.

4053. J. Laing. Improvements in the manufacture of gas from mineral and other oils and tars, and in apparatus therefor. February 26.

4111. J. F. Duke. Improvements in the means for automatically lighting gas. February 27.

4189. C. W. Pinkney. Improvements in and apparatus for the manufacture of gas suitable for use in gas engines or for heating purposes. February 27.

4281. J. Mactear. Improvements in deodorising the exhaust gases from gas or oil motors or engines. February 28.

\* See Note (\*) on previous page.

4283. O. Imry.—From La Société Anonyme des Moteurs Thermique Gardie, France. Process for the manufacture of combustible gas. February 28.

4376. H. Palmer and E. Spain. Improvements in night-lights. March 1.

4506. R. Dunlop. Improvements in treating and utilising certain gases resulting from carbonisation of coal. March 3.

4661. A. MacLaine. Improvements in the combined manufacture of coal-gas and water-gas in gasworks and the carburetting of same. March 6.

4719. E. Fleischhauer and M. Bernstein. Improvements in and relating to the manufacture of gas. Complete Specification. March 6.

4812. W. P. Thompson. Improvements in obtaining or separating certain gases and in apparatus therefor. March 7.

4995. G. Buckley. Improvements in the manufacture of compressed fuel. March 9.

5092. F. Williams. An improved method of using small coke or breeze in the manufacture of coke and coke bricks. March 12.

5214. F. E. Baron. Improvements in liquid fuel and in means or apparatus employed in utilising the same. March 13.

5540. G. Wilton. Improvements in the method of and apparatus for the carbonisation of coal in the manufacture of coal-gas. March 16.

5656. A. Schneller and W. J. Wisse. Improvements in the production of ozone and in apparatus therefor. March 17.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

4475. F. Brunck. Improvements in horizontal coke-ovens. March 7.

4510. F. W. Clark and A. Forbes. Improvements relating to the distillation and breaking up of liquid hydrocarbons and similar substances, and to apparatus therefor. February 28.

5546. P. Drorkovitz. Improvements in the manufacture of coke, coal-gas, and the obtaining of by-products, and in apparatus employed therein. March 14.

8510. J. Moeller. A process for the manufacture of oil-gas. February 21.

23,381. T. Deiches and J. Komaike. Improvements in candles and wax and such like matches. March 21.

23,471. C. C. Walker. Improvements in or connected with the lids of gas retorts or the like. March 7.

1894.

1029. G. St. J. Kneller. Refractory balls and the like for incandescent gas fires or stoves. February 21.

1991. A. J. Boulton. From W. A. Koneman and A. F. Hatch. Process of and apparatus for utilising producer gas as fuel for calcining limestone. March 21.

3223. W. Donaldson. See Class XI.

## IV.—COLOURING MATTERS AND DYES.

## APPLICATIONS.

25,074A. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of a new dihydroxy-naphthalene disulpho acid. February 21.

3026. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of new bases containing sulphur of their sulphonic-acids, and of colouring matters derived therefrom. February 12.

3032. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co., Germany. The manufacture or production of azo dyestuffs. February 12.

3036. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of new mordant-dyeing colouring matters and intermediate products relating thereto. February 12.

3113. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co., Germany. The manufacture or production of colouring matters. February 13.

3301. S. Pitt.—From L. Cassella and Co., Germany. Tris-azo dyestuffs. February 15.

3397. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of new nitrosamine compounds suited for use in the preparation of diazo compounds. February 16.

3474. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of new mordant-dyeing colouring matters. February 17.

3828. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. Improvements in the manufacture of naphtha-zarine and of new intermediate products related thereto. February 22.

3842. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of new bases and their sulpho-acids. February 22.

3843. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of colouring matters. February 22.

3844. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of a new naphthylenediaminedisulpho acid and of colouring matters therefrom. February 22.

3886. W. E. Heys.—From Sandoz and Co., Switzerland. Improvements in the production of colouring matters dyeing with mordants. Complete Specification. February 23.

4373. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co., Germany. The manufacture or production of azo colouring matters. March 1.

4459. S. B. Boulton, T. B. Haywood, H. E. Boulton, and H. Fergusson. Processes for the production of certain salts of beta-sulphonaphthalene and for the separation of alpha- and beta-sulphonaphthalenes. March 2.

4460. O. Imray.—From The Society of Chemical Industry in Basle, Switzerland. Manufacture of polyazo colouring matters. March 2.

4542. R. E. Evans. Manufacture of a new colouring matter. March 3.

4629. H. Imray.—From The Basle Chemical Works, Bindschedler, Switzerland. Manufacture of a new dioxynaphthalene-monosulpho acid and of colouring matters therefrom. Complete Specification. March 5.

4630. H. Imray.—From The Basle Chemical Works, Bindschedler, Switzerland. Manufacture of a new dioxynaphthoic monosulpho acid and of colouring matters therefrom. Complete Specification. March 5.

4870. J. Altschul. Improvements in the manufacture and application of a new diazo compound for use in dyeing and printing. March 8.

4893. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Improvements in the production of phenol-carbon acids. March 8.

5056. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co., Germany. The manufacture or production of colouring matters. March 10.

5143. R. Koreff. Manufacture of new amido bases and of azo colouring matters therefrom. Complete Specification. March 12.

5144. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co., Germany. The manufacture or production of azo colouring matters and materials thereof. March 12.

5159. H. H. Lake.—From Wirth and Co., Agents for A. Leenhardt and Co., Germany. Improvements in the manufacture of colouring matters. March 12.

5267. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co., Germany. The manufacture or production of azo dyestuffs and materials thereof. March 14.

5318. L. Koechl and J. Altschul. Production of new yellow colouring matters. March 14.

5444. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Binding, Germany. Improved manufacture of dry alizarine. March 15.

5546. C. D. Abel.—From A. Fischesser and Co., Germany. Manufacture of naphthylamine 1, 3, 5 trisulpho acid, and of two new naphthylamine 1, 3, 5 trisulpho acids derived therefrom. March 16.

5547. C. D. Abel.—From A. Fischesser and Co., Germany. Manufacture of 1, 8 amidonaphthyl 4, 6 disulpho acid. March 16.

5636. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co., Germany. The manufacture or production of polyazo dyestuffs. March 17.

#### COMPLETE SPECIFICATION ACCEPTED.

1893.

5693. J. H. Ziegler. Manufacture of new colouring matters by the action of diazo compounds on the hydrazine derivatives of oxalylacetic ether. February 21.

6035. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co. The production or manufacture of colouring matters. February 28.

6035A. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co. The manufacture or production of colouring matters. February 28.

7330. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co. The manufacture or production of dye stuffs. March 21.

8181. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. The manufacture of new sulpho-acids of phenylrosinduline and analogues and homologues thereof. February 28.

8221. W. H. Claus. Manufacture of blue colouring matter containing sulphur. March 7.

8824. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co. Improvements in the manufacture or production of basic compounds derived from pyrazine. March 14.

8898. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co. The manufacture or production of colouring matters and materials thereof. March 14.

9689. Read, Holliday, and Sons, Lim., and R. Holliday. The production of new colouring matters for dyeing and printing. March 14.

9894. H. E. Newton.—From The Farbentabriken vormals F. Bayer and Co. The manufacture or production of azo colouring matters. March 21.

9969. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Manufacture of basic colouring matters. March 21.

1894.

2232. W. G. Thompson and I. Moore. Improvements in the manufacture of a diazido base and of tetraazo colouring matters derived therefrom. March 7.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

## APPLICATIONS.

3100. J. Smith and H. F. Clayton. A new method of means for treating yarn slubbing and woven or felted fabrics. February 12.

3103. S. F. Hughes. An improved means for removing grease or other fatty compounds from all raw material used in the manufacture of woollen, cotton, silk, linen, or other fabrics, and the fabrics themselves, as well as to increase the efficiency of oxidising agents when used for the purpose of kaulsing and bleaching. February 14.

3184. O. Reichenbach. An improved process and apparatus for cleaning wool and other textile products. Complete Specification. February 17.

3534. J. V. Eves. Improvements in the treatment of wet spun flax yarn. February 19.

3569. J. Faust. Extracting the fibres out of "ramie-plants" and the like. February 27.

3642. D. Emsley and J. Robinson. An improved method of clearing or preparing rice fibre. February 24.

3644. T. Cheetham. Improvements in means for facilitating the examination of textile fabrics. February 26.

3727. J. Lorraine. Improvements in the strengthening of textile materials or substances subject to tensile strain. February 28.

3832. J. S. Farmer, H. L. Storey, and I. H. Storey. Improvements in the manufacture of solid-colour floor-cloths, and in machinery employed in such manufacture. March 2.

4481. A. Drew. Improvement in treating dyed or printed textile fabrics. March 3.

4665. E. de Pass.—From J. C. McLauchlin and A. A. Hand, United States. Improvements in the manufacture of fabrics from fibre. March 5.

4697. A. Zimmermann.—From J. Hoffert, Germany. Improvements in treating tissues, fibres, paper, and the like. March 6.

4879. J. Anderson, jun. Improvements in the method and means of washing wool and similar substances for extracting greasy, oily, and other fatty matters therefrom and recovering products therefrom. March 8.

5128. J. Harrison and C. Wolfendale. Improvements in and apparatus for the manufacture of inlaid or through-colour floor coverings. March 12.

5150. J. Harrison and C. Wolfendale. Improvements in and apparatus for the manufacture of inlaid or through-colour floor coverings. March 12.

5151. H. S. Close and W. O. Roff. An improved process of retting flax, jute, or other similar fibrous materials and eliminating the gummy or other matter therefrom and utilising the resultant residuals. March 12.

5167. J. Harrison and C. Wolfendale. Improvements in and apparatus for the manufacture of inlaid or through-colour floor coverings. March 12.

5334. R. J. H. Rastick. Improvements in the treatment of reed and other fibrous plants. March 11.

## COMPLETE SPECIFICATION ACCEPTED.

1893.

8717. J. C. Mewburn.—From J. Cardon. Improvements in machinery for breaking, softening, and removing the gummy matter from hemp, ramie, and other fibrous materials. March 7.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

## APPLICATIONS.

3103. S. P. Eastick and W. J. Stonhill. A process for disinfecting, bleaching, and converting rags into a pulpy or "half-stuff" condition. February 13.

3193. S. F. Hughes. See Class V.

3378. W. P. Thompson.—From E. Haefely, Germany. An improved process of dyeing for producing genuine Turkey red and rose colour in yarn hanks and fabrics. Complete Specification. February 16.

5186. G. Keighley. A new or improved means or method of dyeing warp on the beam. March 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

4437. C. Owens and J. Whiteley. Improvements in machines for washing, bleaching, mordanting, dyeing cotton, wool, or other fibres in a raw, spun, or manufactured state. February 28.

5291. Rhodes, Rhodes, jun., and Perkins. Improvements in apparatus for dyeing and washing yarn in the hank. March 7.

7487. Read, Holliday, and Sons, Lim., and H. Bind-schaller. Improvements in the production of an indigo vat or bath employed in the dyeing with indigo. February 21.

7919. Hay and Park. Improvements in dyeing certain colours on cotton fabrics and yarns. February 28.

7841. E. Gessler. Improvements in dyeing apparatus. February 28.

8167. F. R. Wells. A process for colouring paper and cardboard. February 21.

9682. J. Relitt. Improvements in the method of and apparatus for dyeing, mordanting, and otherwise treating woven or felted fabrics and yarns. March 21.

23,559. W. P. Thompson.—From E. Holken and Co. An improved process of dyeing for producing genuine Turkey-red and rose-colour in vegetable yarns in cops, hanks, carded strips, and the like. February 21.

1894.

3378. W. P. Thompson.—From E. Haefely, Germany. An improved process of dyeing for producing genuine Turkey red and rose colour in yarn hanks and fabrics. Complete Specification. February 16.

## VII.—ACIDS, ALKALIS, AND SALTS.

## APPLICATIONS.

3637. J. Brock, V. C. Driffeld, A. Carey, and F. Brown. Improvements in and apparatus for the treatment of "caustic salts" obtained as a by-product in the manufacture of caustic soda. February 12.

3372. S. Z. de Ferranti and J. H. Noad. Improvements in the manufacture of oxides and carbonates of lead. February 16.

3560. F. W. Golby.—From L. Schrader, Germany. A process for making chloride of strontium from sulphate of strontium. February 19.

3571. F. Ilavati and F. Sladky. Processes for the production from air, with or without admixture of oxygen, of nitric acid, nitrates, and other nitrogen salts; also the production from air, together with water-gas or hydrogen of ammonia, and compounds thereof. February 19.

3767. H. R. Angel. Improvements in the manufacture of carbonic acid gas, bicarbonate of soda, and metallic sulphur. February 21.

4013. A. R. Davis. Improvements in the distillation of ammonia. February 24.

4034. W. Mills. Improvements in the manufacture of soda and potassa. February 26.

4341. G. Foulcr. Improvements in and apparatus for the manufacture of ammonia, and of by-products obtained therein. March 1.

4423. R. Wolfenstein. Improvements in the development or preparation of high percentage and of chemically-pure super-oxide of hydrogen. March 2.

4573. W. Garraway. Improvements in the manufacture of caustic soda, nitric and sulphuric acids. March 5.

4791. H. Wächter. A bleaching preparation or mixture applicable also for other purposes. Complete Specification. March 7.

4916. A. J. Boulton.—From E. Warzee, Belgium. Process for the separation and precipitation of salts of iron and zinc from solutions containing both. Complete Specification. March 8.

5168. J. Y. Johnson.—From J. Marx, Germany. Improvements in or connected with the manufacture of plumbates and plumbic acid (peroxide and other oxides of lead). March 12.

5178. M. W. Beylikgy. A new and improved process of manufacturing alkaline bichromates. March 13.

5237. R. Campion. Improvements in the production of soda. March 13.

5300. W. Mills. Improvements in utilising spent iron pyrites and apparatus therefor. March 14.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

4310. A. Gray. See Class X.

7485. F. M. Spence, D. D. Spence, and J. Gilchrist. Improvements in certain apparatus for the distillation of ammoniacal liquor. March 7.

7512. J. Brock and F. Hurter. Improvements in the manufacture of permanganates of soda or potash from manganates of soda or potash. February 21.

7846. C. Raspe. Improved process for the manufacture of carbonate of ammonia. February 21.

8907. H. R. Browne and M. Guthrie. Improvements in the manufacture or production of soda crystals. March 7.

9271. G. S. Albright and J. J. Hood. Improvements in the manufacture of manganese peroxide. March 14.

12,997. La Société Marcheville Daguin and Co. Improvements in calcining apparatus for the conversion of bicarbonate of soda into carbonate of soda, and other uses. March 14.

#### VIII.—GLASS, POTTERY, AND EARTHENWARE.

##### APPLICATIONS.

3677. J. Hawthorn. Improvements in pottery kilns. February 20.

3695. E. H. Pearce, J. Brettell, and G. Thomas. Improvements in the art of glass decoration. February 21.

4081. C. Margot. An improved process for producing indelible ornamentations upon glass or glazed surfaces. February 26.

#### COMPLETE SPECIFICATION ACCEPTED.

1893.

4385. H. Hilde. Improved method and machinery for blowing and casting articles of glass. February 21.

#### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

##### APPLICATIONS.

3496. L. Tabbatt. New method of covering bricks, walls, and similar surfaces with a glazed or enamelled surface. February 14.

3738. J. McDonnell. Improved method of making bricks for street and other paving from fibre or fibrous waste and bitumen or asphalt or similar substances. February 21.

3843. T. D. Harries. An improved artificial stone. Complete Specification. February 22.

4223. P. Baumert and A. Pieck. Improvements in the manufacture of artificial stone or marble. Complete Specification. February 28.

4275. F. Turner. A novel compound adaptable as a cement. February 28.

4377. R. Astley. Improvements in the construction of fireproof floors. March 1.

4632. A. Kuhnwein. Manufacture of asbestos cement and of coverings or moulded objects made therefrom. March 5.

5071. G. W. A. Stein. Improved process of manufacturing hydraulic cement. Complete Specification. March 10.

5137. E. Benard. Improvements in the manufacture of cements. March 12.

5160. C. J. Potter. An improved material for paving and like purposes. March 12.

5590. J. I. Cox. Improvements in fire-clay and other bricks. March 17.

5595. C. A. Ropes and J. C. Sellars. Improvements in or connected with cements or cement work. March 17.

5626. T. L. Banks. Improvements in the construction of fireproof floors. March 17.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

7499. W. Sykes. Improvements in the manufacture of compositions suitable for paving, building, pipe-jointing, and other like purposes. February 28.

7501. R. Astley. An improved form and method of construction of fireproof floors. February 21.

8441. N. Rigby. An improved material for covering or decorating walls and the like, and the method of producing the same. February 28.

9044. H. H. Leigh.—From A. Jumeau. Improvements in the mosaic reproduction of decorative painting. March 14.

16,415. W. A. Barr. Improvements in and connected with fireproof ceilings. February 21.

1894.

477. G. W. A. Stein. Improved method of manufacturing hydraulic cement. March 14.

1396. H. H. Leigh.—From G. Bagge. Improvements in paving blocks. February 28.

#### X.—METALLURGY, MINING, Etc.

##### APPLICATIONS.

3224. J. M. White. Improvements in the manufacture of steel or iron plates and apparatus therefor. February 14.

3228. J. W. Swan. Improvements in and apparatus for desilverising lead. February 14.

3680. J. Nicholas. Improvements in obtaining gold and silver from ores and other compounds, and apparatus therefor. February 20.

3711. H. J. Phillips. A method of preparing, desulphurising, and carbonising bricks, for a process of desulphurising and carbonising molten iron or steel in one operation. February 21.

3705. F. Tscherrin. Manufacture of metallic alloys and mechanical mixtures of metals of high specific gravity, applicable for projectiles and cores of projectiles. February 23.

3936. W. F. Reid. A new or improved process and material for the production of articles of metal. February 24.

3991. J. Bedford. Improvements in the manufacture of steel and in alloys for use therein. February 24.

4199. H. W. Gabbett-Fairfax and W. Beardmore. Improved method of and apparatus for hardening or tempering steel plates and other articles. February 27.

4335. J. Stuart and J. Mason. Improvements in the production of aluminium. March 1.

4533. T. Hampton. Improved method of and moulds for casting compounds, ingots for armour plates and other plates. Complete Specification. March 3.

4761. C. T. J. Oppermann. Improvements in and connected with the deposition of metals upon aluminium. March 7.

4840. G. Hookham. A new metallic alloy for cartridge cases and articles subjected to high temperatures. March 7.

4980. W. P. Thompson.—From O. Nicolai, Germany. A new or improved solder for soldering aluminium, aluminium alloys, and other metals. Complete Specification. March 9.

5090. E. C. Broadwell. Improvements in soldering materials for aluminium. March 10.

5235. D. Blyth. Improvements in the treatment of iron ores for use in the manufacture of steel, for purifying and other purposes. March 13.

5345. J. A. Mays. Improvements in apparatus for oxidising comminuted lead or zinc. March 14.

5346. J. A. Mays. Apparatus for comminuting and converting molten materials. March 14.

5379. W. D. Allen. An improved furnace for treating ingots, blooms, or billets of iron or steel. March 14.

5525. C. W. Buckle and J. Stuart. A new or improved metallic alloy. March 16.

5530. E. Singer, F. Donat, and P. Kircheisen. Process for soft-soldering aluminium. Complete Specification. March 16.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

4310. A. Gray. Improvements in and relating to the manufacture of zinc oxides. February 28.

5218. J. S. McArthur.—From The Cassel Gold Extracting Company, Limited, and C. J. Ellis. Improvements in extracting gold and silver from ores and the like. March 14.

6219. H. Wild. Improvements in or relating to the "Thomas" metallurgical process. February 28.

7453. W. Wilkinson. Improvements in ingot moulds, and in the process of casting hollow metal ingots. February 21.

7730. A. Longsdon.—From L. Grambow. A new or improved process for treating steel armour plates. February 21.

8057. A. Sattmann and A. Homatsch. Improvements in the manufacture of iron and steel. February 28.

8456. B. H. Thwaite. Improvements in the manufacture of steel and in the refining of fluid iron. March 14.

9085. S. Meredith. Improvements in puddling furnaces used in the manufacture of iron and steel. March 14.

9406. J. H. Ladd. Improvements in treating malleable or wrought iron. March 14.

12,825. R. Lewis and G. Morgan. Improvements in apparatus for coating iron and steel plates with tin or other metals or alloys. March 14.

25,071. A. Trug. Method and apparatus for extracting gold and silver from their ores by the combined action of amalgamation and centrifugal force. March 21.

1894.

2041. J. C. Fell.—From The Emmens Zinc Company. Improvements in the treatment of zinc-lead-sulphide ores carrying gold or silver or gold and silver. March 7.

#### XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

##### APPLICATIONS.

3223. W. Donaldson. Improvements in heating of gases by electricity. Complete Specification. February 14.

3674. W. H. Longsdorf.—From G. Hewett, United States. Improvements in primary galvanic batteries and in the liquids used therein. February 20.

3725. T. Blackhurst. Dry or semi-dry galvanic elements. February 21.

3749. A. J. Boulton.—From C. Cudell, I. Cudell, and M. Cudell, Germany. Improvements in galvanic batteries. February 21.

3922. M. Roskell. Improvements in or relating to the electro-deposition of metals. February 23.

4113. H. T. Barnett. Improvements in electric batteries. February 27.

4168. A. W. Hussey. Improved construction of electric battery. February 27.

4325. A. H. Harris. Improvements in the electro-deposition of aluminium. March 1.

4472. T. Parker. Improvement in electrolytic processes in the manufacture of chlorine alkali and derived products. March 3.

4635. H. Wehmann. Improvements in galvanic batteries. March 5.

4724. O. March. Improvements in and relating to secondary batteries. March 6.

5537. R. Heathfield and W. S. Rawson. Electrical deposition of zinc and alloys of zinc, and apparatus therefor. March 16.

5579. J. Kirkwood. Improved solutions for the electric deposition, separation, and refinement of aluminium. March 17.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1892.

23,101. C. A. J. H. Schroeder and H. E. R. Schroeder. New primary batteries. March 21.

1893.

1114. A. W. Armstrong. An improvement in the electrodes of electric, galvanic, and other batteries. February 21.

5197. J. Hargreaves and T. Bird. Improvements in the production of alkali and in apparatus therefor, the said apparatus being applicable for electrolysis generally. March 14.

5198. J. Hargreaves and T. Bird. Improvements in and in making electrolytic apparatus. March 14.

7594. F. M. Lyte. Improvements in the electrolytical decomposition of chlorides and mixtures thereof, and in apparatus for the purpose. March 7.

8571. H. C. W. Emery. Improvements in or connected with cells for electric batteries. March 7.

10,584. H. Y. Castner. Improvements in connection with electrolytic apparatus. March 14.

10,942. W. Walker, jun., and F. R. Wilkins. Improvements in primary voltaic batteries. March 24.

23,881. W. P. Thompson.—From C. L. Coffin. Improved apparatus for heating metals electrically. March 7.

24,274. C. Kellner. Improvements in apparatus for the electrolytic decomposition of metallic salts. March 7.

24,871. H. T. Johnson. Improvements in dry batteries. February 21.

1894.

2900. J. Rudholzner. Improvements relating to the electro-deposition of metals. March 14.

3223. W. Donaldson. Improvements in the heating of gases by electricity. March 14.

### XII.—FATS, OILS, AND SOAP MANUFACTURE.

#### APPLICATIONS.

3025. C. Weygang. Manufacture of saponaceous products from petroleum. February 12.

3197. H. Lambert. Improvements in the method of and machinery or apparatus for extracting oil from seeds and the like, and for forming cakes from such or any suitable substance. February 14.

4622. R. Andrew. Improvements in purifying liquids and fats, and apparatus therefor. March 5.

4819. A. Blackie. Improvements in preparing, packing, and dissolving mixed powders to form liquids or washes, suitable for dipping animals and for washing or syringing plants for destroying germs, parasites, and mildew, and for other uses. March 7.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

7742. J. E. Bedford and C. S. Bedford. Improvements in the manufacture of linoleum oil. February 28.

8621. H. Hamilton. A new or improved composition of soap. February 21.

12,884. C. R. Illingworth. A superfatted biniodide of mercury soap. March 21.

18,658. J. Mellinger. Improvements in soap for removing hair from the skin. February 21.

### XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

#### APPLICATIONS.

3372. S. Z. de Ferranti and J. H. Noad. See Class VII.

4059. J. Masters. A special preparation of rubber. February 26.

4201. F. A. W. Sly. An improved manufacture of varnish. February 27.

4505. J. S. Macarthur. New or improved composition for varnishing or polishing. March 3.

5168. J. Y. Johnson.—From J. Marx, Germany. See Class VII.

5347. J. A. Mays. Process of and apparatus for the manufacture of white lead. March 14.

5414. A. R. von Pischof. An improved process for manufacturing a permanently elastic substance. March 15.

5440. E. Hérisse. An elastic composition for moulds, waterproofing, and other purposes. March 15.

5608. J. D. Noble. A new or improved fireproof and insulating paint. March 17.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

1113. S. J. Simpkin. Improvement in the manufacture of refined indigo. February 21.

3886. W. M. Walters. Improvements in the composition and treatment of substances for use as glue, putty, and cement. February 28.

7119. A. C. J. Charlier. Improvements in apparatus for the manufacture of metallic pigments or compounds, and in the production of lead and zinc pigments or compounds, and combinations of these by means of such apparatus. March 14.

9611. W. P. Thompson.—From G. Leuchs and C. Leuchs. Improvements in the manufacture of glazes, enamels, and the like. March 21.

1894.

166. O. Inray.—From J. Sachs, C. E. Meier, and M. Gerstenborfer. Improvements in the manufacture of pigments. March 14.

### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

#### APPLICATIONS.

3615. E. H. Lewis. Improvement in the art or process of waterproofing leather and in the compounds employed in same. Complete Specification. February 20.

3616. E. H. Lewis. Improvement in the art or process of waterproofing leather. Complete Specification. February 20.

4193. A. Levinstein. Improvements in the tanning of hides. February 27.

4679. H. Walker and J. J. Wilson. A new or improved process in or connected with the currying of skins and appliances therefor. March 6.

4696. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering, Germany. Improvements in the treatment and testing of gelatinous matter. March 6.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

3886. W. M. Walters. See Class XIII.

21,088. T. J. W. Mackenzie and W. J. Nodin. A new ornamental leather and process for preparing the same. March 21.

1894.

2079. G. E. Wiese. Improvements in the manufacture of liquid glue. March 7.

2175. J. Grillo and M. Schroeder. Process for the production of glue and gelatin from bones. March 7.

### XV.—AGRICULTURE AND MANURES.

#### APPLICATIONS.

4988. E. E. Dietz. Improvements in the manufacture of phosphatic slags of a high percentage of soluble phosphate with or without magnesia or potash. March 9.

5517. D. Blyth. Improvements in the preparation of manures. March 16.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

7637 W. Brothers. Improved manure or fertiliser. February 21.

1894.

2624 J. J. Seldner and J. Watson, jun. Improvement in the manufacture of fertilisers. March 14.

## XVI.—SUGARS, STARCHES, GUMS, Etc.

## APPLICATIONS.

3733. T. Sheldon. Improvements applicable to treacle, honey, and similar viscous syrups. February 21.

3782. E. Langen. Improvements in refining sugar. Complete Specification. February 21.

3813. G. Pott. Improvements in apparatus for mixing and heating or cooling moist sugar or like substances. February 22.

5119. D. Drummond. See Class I.

5512. E. Leconte. Process for purifying and decolorising saccharine juices in the manufacture of beetroot and other sugar. March 16.

5518. D. Blyth. Improvements in the method of purifying and decolorising saccharine, amylaceous, and other fluid bodies. March 16.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

3170. J. A. Morrell and J. Fromberz. See Class I.

5793. J. Hanson, P. C. D. Castle, and J. H. Morrison. Improvements in or appertaining to the utilisation of a waste or nearly waste product, and the manufacture of a useful gum or gummy compound therefrom. March 7.

## XVII.—BREWING, WINES, SPIRITS, Etc.

## APPLICATIONS.

3055. L. L. Thomas. Solidified herb beer extracts and wine essences. February 13.

3076. D. A. Blair. Improvements in and relating to continuous working spirit stills. February 13.

3296. J. B. Bouyoud and A. Vellnet. Waterless liqueur. February 15.

3642. J. C. Pennington. Improved process for the manufacture of beer. Complete Specification. February 20.

3997. C. Rach. Apparatus for the preparation of wort. February 24.

3998. C. Rach. Apparatus for brewing. February 24.

4678. C. P. Hendy. Apparatus to prevent waste when fining beers and ales in casks. February 26.

4894. P. Pavrez. Apparatus for pasteurising or sterilising and cooling beers, and for aerating or charging beers with gas before placing them in cask or in bottle. Filed March 8. Date claimed August 23, 1893, being date of application in France.

5618. G. H. U. Harrow. Improvements in brewing and distilling. March 17.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

6168. G. de Geyter. Improvements relating to the saccharification of wort or the like, and to the extraction and subsequent treatment thereof in brewing, distilling, and in the manufacture of maltose, syrups, and other extracts, and apparatus therefor. March 21.

16,063. G. Morris and W. Edney. An improved still or apparatus for distilling spirits and all kinds of other liquids. March 14.

24,548. R. George. Improvements in the preparation of malt and in apparatus therefor. March 7.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

## APPLICATIONS.

*A.—Chemistry of Foods.*

3413. R. C. Wilson. Improvements in or connected with the manufacture of salt. February 17.

3791. J. F. Duke and A. Foucard. An improved method of treating preserved eggs. February 22.

4049. A. L. Lebet. An improved food compound having for its base milk. February 26.

4050. A. L. Lebet. An improved food compound having for its base milk. February 26.

4193. F. Goracci and A. Anselmi. A new or improved compound for use as an ingredient for soup or other food. February 26.

4548. J. Raschen. Improved substitutes for butter and lard. March 3.

4977. E. W. Beech and T. Wilson. Improved means, method of, and appliances for the preservation of food extracts. March 9.

*B.—Sanitary Chemistry.*

3333. W. Ambler. Improvements in the method of and apparatus for annihilating fumes emitted from destructors for destroying towns' refuse and the like. February 16.

3969. H. Lockwood. Improvements in the purification of sewage and other foul waters. February 24.

4169. A. J. Bonlt.—From F. S. Salberg, England, and M. Neumann, Austria. A sanitary process and apparatus for towns and trades. Complete Specification. February 27.

4195. H. H. Lake.—From Seaburg and Johnson, United States. Improvements relating to the burning of sulphur for disinfecting purposes. Complete Specification. February 27.

4210. J. Brierley. Improvements in filters for treating sewage or other refuse or fouled waters. February 28.

4725. H. Rieusch. Improved plant for purifying waste water. March 6.

4727. E. H. L. Ostermann. Improved process for purifying waste waters. March 6.

5105. E. C. Ives. Improved means or apparatus for purifying sewage or other foul or polluted waters. March 12.

*C.—Disinfectants.*

5066. R. J. Stephens and J. Hewes. Improvements in or relating to disinfectants and deodorants. March 10.

5288. A. Kraus and A. Chevrier. An improved manufacture of an antiseptic and microbicide. March 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

*A.—Chemistry of Foods.*

1893.

15,161. W. F. E. Casse. Process for preserving milk and cream for a length of time, rendering it suitable for lengthy transit. March 14.

1894.

1170. R. F. Maclosky.—From J. H. Niemann. A new or improved meat extract. March 21.

**B.—Sanitary Chemistry.**

1893.

6423. J. I. Meldrum and T. F. Meldrum. Improvements in or connected with the purification of sewage and analogous foul or impure liquids. March 7.

9063. R. C. Tanner. A new or improved method of treating sewage by means of ferric compounds. March 21.

**C.—Disinfectants.**

1893.

6553. P. Molyneux and G. R. Potts. Improvements in or connected with disinfectants. March 7.

8129. S. Pitt.—From The Chemische Fabrik auf Actien vormals E. Schering. Improvements in the preparation of antiseptics. March 7.

24,709. S. F. Kattenhoy. Apparatus for the production of ozone from phosphorus for disinfecting purposes. March 7.

**XIX.—PAPER, PASTEBOARD, Etc.**

**APPLICATIONS.**

3103. S. P. Eastick and W. J. Stonhill. A process for disinfecting, bleaching, and converting rags into a pulpy or "half stuff" condition. February 13.

3105. J. Baier and R. W. Baxter. Improvements in the manufacture of imitation whalebone. February 13.

3440. E. Partington. Improvements in the treatment of "sulphite pulp" used in the manufacture of paper and the like from wood. February 17.

3906. C. Beadie. A process for treating paper so as to provide against falsification of documents. February 23.

4697. A. Zimmermann.—From J. Hoffert, Germany. See Class V.

5054. A. E. Healey and J. Williams. Improvements in treating paper and other fabrics, and in the preparation of solutions for that purpose, and the obtaining of a by-product in the said preparation. March 10.

5557. P. W. Wilkinson. An improved manufacture of paper for bank notes and other documents. March 16.

**COMPLETE SPECIFICATIONS ACCEPTED.**

1893.

9827. S. Wheeler. Improvements in the manufacture of paper and like materials. March 21.

23,502. W. P. Thompson.—From C. Schauffelen. An improved finely-granulated paper and process of producing the same. March 21.

24,275. C. Kellner. Improvements in the manufacture of cellulose. March 7.

24,287. C. Kellner. Improvements in the manufacture of cellulose. March 14.

1894.

824. W. White. An improved method of preparing pigment paper for photographic printing. February 21.

**XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.**

**APPLICATIONS.**

3055. L. L. Thomas. Solidified herb beer extracts and wine essences. February 13.

3179. S. Radlauer. A new or improved anti-pyretic and anti-neuralgic preparation. Complete Specification. February 14.

3290. J. B. Bonyard and A. Velluet. See Class XVII.

3553. R. Haddan.—From C. Strohler and Co., Germany. A new or improved herbal extract and process of producing the same. February 19.

4018. W. Malthmann. An improved manufacture of ketone musk. Complete Specification. February 24.

4997. J. A. Johnson.—From C. F. Boehringer and Sohn, Germany. The treatment of ergot of rye and the production therefrom of the substance which imparts to it its valuable properties. February 26.

**COMPLETE SPECIFICATIONS ACCEPTED.**

1893.

8735. J. C. W. F. Tiemann. Manufacture of a new chemical substance from orris-root. March 14.

8736. J. C. W. F. Tiemann. Manufacture of new chemical substances suitable for perfumery, confectionery, and the like. February 28.

1894.

684. F. W. Warrick. An improvement in capsule fillings containing ferrous salts. February 21.

3179. S. Radlauer. A new or improved anti-pyretic and anti-neuralgic preparation. Complete Specification. February 14.

**XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.**

**APPLICATIONS.**

3121. M. Russo and G. B. Zanardo. A process for the production of objects, either in relief or in intaglio with the aid of photography. February 13.

4276. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering, Germany. Improvements in the manufacture of photographic printing plates. February 28.

4346. F. Slavin and S. Pollastrini. A new or improved method or means of photographing in colours. March 1.

4606. C. E. Pettitt. Improvements in the manufacture of sensitive plates and films for photographic purposes. March 5.

4627. T. H. Blair and The European Blair Camera Company, Limited. Improvements in or relating to appliances for the manufacture of photographic films. March 5.

4689. J. R. C. Gale and J. W. T. Cadett. Improvements in the preparation, packing, and storing of photographic chemical compounds. March 6.

5061. S. H. A. Oakes and R. R. Gibbs. Improvements in or appertaining to photographs. March 10.

5511. T. Moore. New method of reproducing prints from photographic negatives. March 16.

5561. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering, Germany. Improvements in photography. March 16.

**COMPLETE SPECIFICATIONS ACCEPTED.**

1893.

5504. A. J. Boulton.—From T. H. Blair. Improvements in or relating to the manufacture of films for photographic purposes. March 21.

1894.

824. W. White. See Class XIX.

## XXII.—EXPLOSIVES, MATCHES, ETC.

## COMPLETE SPECIFICATIONS ACCEPTED.

## APPLICATIONS.

3024. C. D. Abel.—From L. König, Germany. Improved manufacture of explosives from nitrate of ammonia and resins. Complete Specification. February 12.

3773. E. Hesketh and A. Mareet. Improvements in or connected with the manufacture of gun-cotton or other manufactures in which cooling water liable to become acidulated is employed. February 21.

4543. E. de Poorter, A. Walton, and T. H. Andreal. The manufacture of an improved smokeless explosive compound. March 3.

4626. A. Manrette. An explosive composition. Complete Specification. March 5.

1893.

22,992. H. C. Seddon. Improvements in percussion fuses for projectiles. March 21.

23,381. T. Deiches and J. Komaike. See Class II.

1894.

1982. V. I. Feeny.—From The United States Smokeless Powder Co. Smokeless powder. March 7.

3024. C. D. Abel.—From L. König, Germany. Improved manufacture of explosives from nitrate of ammonia and resins. Complete Specification. February 12.

## NOTICES.

In accordance with the provisions of Rule 18 of the By-Laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list, will retire from their respective offices at the forthcoming Annual General Meeting.

Dr. T. E. Thorpe, F.R.S., has been nominated to the office of President; and Mr. E. C. C. Stanford has been nominated Vice-President under Rule 11.

Mr. John Calderwood, Dr. C. Dreyfus, Dr. A. Dupré, F.R.S., and Prof. W. A. Tilden, F.R.S., have been nominated Vice-Presidents under Rule 8; and Mr. Wm. Thorp has been nominated an Ordinary Member of Council under Rule 17, in the place of Dr. C. Dreyfus, nominated a Vice-President.

## THE JOURNAL.

### Publication Committee:

The President.

A. H. Allen.	Prof. A. K. Huntington.
L. Archbutt.	F. Hurter, Ph.D.
G. H. Bailey, D.Sc., Ph.D.	C. Clarke Hutchinson.
Joseph Bernays, M.I.C.B.	Wm. Kellner, Ph.D.
H. Brunner.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
W. Y. Dent.	John Pattinson.
Chas. Dreyfus, Ph.D.	W. H. Perkin, Ph.D., F.R.S.
Sir John Evans, K.C.B., F.R.S.	H. R. Procter.
Percy Gilchrist, F.R.S.	Boverton Redwood.
John Heron.	John Spiller.
D. B. Hewitt, M.D.	Wm. Thorp.
David Howard.	Thomas Tyrer.
Prof. J. J. Hummel.	

Mr. C. A. FEARNS has been nominated an Ordinary Member of Council under Rule 24, and the Treasurer and Foreign Secretary have been nominated for re-election to their respective offices.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

*Extract from Rule 18:*—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrears with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

#### ALTERATION OF BY-LAWS

Notice is hereby given, in accordance with Rule 54 of the By-Laws, that the Council will propose to the forthcoming Annual Meeting the amendment of the Society's By-Laws as follows:—

1. That *Rule 7* be amended by the deletion of "and" in the first line thereof, and by the addition of the words "and 47" in the same line.

2. That *Rule 15* shall read as follows:—

"Four Ordinary Members of Council shall retire each year, and those who thus retire shall not be eligible for re-election to the Council, except under By-laws 14, 23, and 24, until the Annual General Meeting next following that at which they retire. When an Ordinary Member of Council is nominated for election to the office of President, he shall not be counted among those who are to retire."

3. That the first sentence of *Rule 16* read as follows:—

"Except that any Ordinary Member of Council may be nominated for election to the office of President, and that such member, if any, shall not be included in the operation of the present By-law, the Ordinary Members of Council shall retire as far as may be possible in the order in which they were elected."

4. That *Rule 17* shall read as follows:—

"When an Ordinary Member of Council is nominated for election to the office of President, the Council shall nominate a Member for election as an Ordinary Member of Council in his place."

5. That under *Rule 18* the eighth line be amended to read as follows:—"and also the name of the person, if any, who has been nominated, &c., &c."; that the form of nomination of candidates for the Council be amended by transferring the candidate's declaration to the end thereof; and that the words "and by the nominee" be added in the third line after the above-mentioned form after the word "subscriptions."

6. That the proviso at the end of *Rule 22* be deleted.

7. That in *Rule 26* the Nomination Form for candidates for Membership be amended to read as follows:—

"We, the undersigned members of the Society of Chemical Industry, hereby propose  
(candidate's name in full) as a fit and proper person to become a member of the Society.

For names only of members }  
recommending the candidate. }

"And I, the said candidate for membership, hereby declare that if elected I will do my best to support the Society and will observe its By-Laws.

(Signature) \_\_\_\_\_ (Profession) \_\_\_\_\_

(Address) \_\_\_\_\_ (Date) \_\_\_\_\_

*Extract from By-Laws (Rules 27, 29, and 30).*

8. That *Rule 27* should read as follows:—

"Each member shall pay an annual subscription of, twenty-five shillings, due on the 1st January in each year; except that any member may pay a life composition fee of twenty pounds in lieu of an annual subscription. He shall also pay on receipt of notice of election an entrance fee of one guinea in addition to his first year's subscription; except that should a member who has paid an entrance fee resign and subsequently seek re-election the Council may dispense with a further entrance fee."

9. That in the second line of *Rule 28* the words after "and" read as follows:—"issued to the members once every year."

10. That *Rule 29* read as follows:—

"No person shall be entitled to the privileges of membership who has not paid his subscription for the current year. He shall not attend meetings nor vote, nor shall he receive gratuitously the publications of the Society. Should the subscription remain unpaid eight months after it is due, the Secretary shall give the member notice that unless payment be made within four months after the date of such notice, his name will be struck off the register. At the expiry of the said period, if the member should still remain in default, the Council may order his name to be removed from the register, whereupon he shall cease to have any right, privilege, or interest in the Society, and the Council may notify the same in the Journal and recover the arrears of subscription at law."

11. That *Rule 30* read as follows:—

"Any member may withdraw from the Society at the end of any year by giving previous notice to the General Secretary of his intention to withdraw; always provided that such notice to be valid must be accompanied by the payment of all subscriptions, if any, which may be due from him to the Society at the date of the notice. By such notice and payment he shall be released from all further liability as a member."

12. That the following Rule be added after *Rule 53* of the present Rules:—

"All communications between Local Sections and Public Bodies or Societies shall be conducted through or be at the discretion of the Council; and no publication shall be issued by any Section to the general public without the previous consent of the Council."

13. That *Rules 54* and *55* be placed after *Rules 34* and *38* respectively, and that the succeeding Rules be renumbered accordingly."

#### ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in Edinburgh on the 18th, 19th, and 20th July next. An outline draft of the programme will appear in the May issue. Tickets of membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

#### BANKERS' ORDERS.

For the convenience of Members, the Treasurer has arranged with the Bankers of the Society that they shall collect subscriptions from Bankers in town and country, and Members, who have not already done so, are invited to fill up and sign the Banker's Order enclosed with the December number of the Journal, which should then be sent to the Honorary Treasurer, Mr. E. Rider Cook, East London Soap Works, Bow, E.

## INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

We are requested by the Foreign Office to state that an International Congress, under the patronage of the Belgian Government, will open in Brussels on the 4th August next, in connection with the Antwerp Exhibition, on the subject of applied Chemistry.

The work of the Congress will be divided into four sections corresponding to those of the Belgian Chemists' Association, viz.:—Sugar, Agricultural Chemistry, Food-stuffs, and Biological Chemistry.

Those who desire to attend the Congress should apply to M. Sachs, 68, Rue d'Allemagne, Brussels (Sugar and Agricultural Chemistry), or to M. H. van Laer, 15, Rue de Hollande, Brussels (Adulteration of Food-stuffs, and Biological Chemistry), who will forward full particulars on application.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

## LIST OF MEMBERS ELECTED 23rd APRIL 1894.

Barnsley, G., jun., Broomfield, Sheffield, steel manufacturer.

Blackmore, H. S., 206, South 9th Avenue, Mount Vernon, N.Y., U.S.A., chemist.

Coward, Percy, 68, Brundett's Road, Chorlton-cum-Hardy, Manchester, chemist.

Gemmell, G. H., 4, Lindsay Place, George IV. Bridge, Edinburgh, chemist.

Heriot, Jas., 18, Dumbiedykes Road, Edinburgh, mineral water manufacturer.

Johuston, G. L., Kingswood, Kingswood Road, Sydenham Hill, S.E., student.

Johnston, W. E., Kingswood, Kingswood Road, Sydenham Hill, S.E., student.

King, W. Grant, Cornell University, Ithaca, N.Y., U.S.A., chemical engineer.

Lazarus, Jos., Opern Ring 13, Vienna, Austria, civil engineer.

Mitchell, Robt., 4, Marchhall Road, Edinburgh, gas engineer.

Sawyer, Harris E., Chemical Laboratory, Harvard College, Cambridge, Mass., U.S.A., instructor in chemistry.

Skelton, J. R., Thorpe St. Andrew, Norwich, technical chemist.

Swan, David, c/o The Swan Colour Co., Ltd., Petershill Road, Glasgow, colour manufacturer.

Thackray, R. B., Laurel Bank, Newby Wood, Horsforth, Leeds, leather manufacturer.

Topley, Wm., F.R.S., Geological Survey Office, 23, Jernyn Street, London, S.W., geologist.

Uhlig, E. C., Millville, Cumberland Co., N.J., U.S.A., glassworks chemist.

## CHANGES OF ADDRESS.

Baly, E. C. C., 10 London; Ardmore, Ritherden Road, Tooting, S.W.

Barratt, W. S., 10 Moss Side; St. Margaret's Schools, Whalley Range, Manchester.

Bell, Percy Carter, 10 Park Row; 13, Ann Street, Park Row, New York, U.S.A.

Bhaduri, K., 10 Baroda; c/o S. K. Lahiri and Co., 51, College Street, Calcutta, India.

Boulton, T. S., 10 Seven Sisters Road; 14, Freegrove Road, Caledonian Road, N.

Brown, Horace T., F.R.S., 10 Add'son Road; 15, Cromwell Crescent, Earl's Court, Kensington, S.W.

Burnham, J. C., 10 Lewisham; Gunpowder Factory, Kirkee, near Poona, India.

Buttfield, H. V., 10 Clapton; 13, Wellington Road, Bush Hill Park, Enfield, N.

Coste, F. H. Perry, 10 Great Tower Street; 142, Burnt Ash Hill, S.E.

Crossley, L., 10 Liverpool; Beachwood, Arnside, Carnforth.

Davis, A. R., 10 Kuntsford; Lynton, Wellington Road North, Stockport.

Dixon, M. T., 10 Newcastle; P.O. Box 1816, Johannesburg, S.A.R.

Dysen, Herbert, 10 Tamworth; 2, Exchange Place, Middlesbrough.

Homfray, D., 10 South Street; 6, Dartmouth Row, Greenwich, S.E.

Houston, R. S., 10 Glasgow; Briar Villa, Greenlaw Drive, Paisley.

Jackman, E. J., 10 Beckton; c/o London County Council, 40, Craven Street, W.C.

Jenkins, T. H., 10 Manchester; c/o Mrs. Waite, Lindow Street, Lancaster.

Jones, Professor D. E., 10 Stafford; 7, Marine Terrace, Aberystwith.

Lewis, G. T.; Journals to 505, Provident Building, South and Chestnut Streets, Philadelphia, Pa., U.S.A.

Macfarlane, R. F., 10 Heaton; c/o Northumbrian Chemical Co., Ltd., Heworth Shore, Felling-on-Tyne.

McGeorge, A. J.; Journals to 215, West 78th Street, New York City, U.S.A.

McMillan, W. G., 10 Calcutta; Metallurgical Laboratory, Mason College, Birmingham.

Marchlewski, Dr. L., 10 Peru Street; 25, Wellington Street, Higher Broughton, Manchester.

Matos, L. J., 10 Fairmount Avenue; 850, Union Street, Philadelphia, Pa., U.S.A.

Morgan, J. J., 10 Milton Lodge; Riverdale, Abergavenny.

O'Sullivan, Jas., 10 Spring Terrace; 26, Ashley Road, Burton-on-Trent.

Ray, Wm., 10 Sloane Street; 141, Duke Street, Chorlton Road, Manchester.

Rideal, Dr. S., 10 St. George's Hospital; 28, Victoria Street, Westminster, S.W.

Roberts, Ernest H., 10 Wicklow; 15, Herndon Road, East Hill, Wandsworth, S.W.

Roberts, J. H. M., 10 Trinity Square; 14, St. James' Road, Brixton, S.W.

June 4th:—

Mr. W. G. McMillan:  
(a.) "Experiments on the Strength of Leather."  
(b.) "Note on the Colour of Brass."  
Dr. P. Dvorkovitch. "Distillation of Peat."

*Meeting held Monday, April 2nd, 1894.*

MR. WM. THORP IN THE CHAIR.

#### COLORIMETRIC ANALYSIS, OR COLOUR AS A MEANS OF QUANTITATIVE ESTIMATION.

BY JOSEPH W. LOVIDOND.

I HAVE the honour to bring under the notice of this Society some observations bearing on the variation of colour as a means of quantitative estimations.

The object of the paper is an attempt to measure the relation between changes of colour in substances, and their causes, whether the causes be of a chemical, or of a physical nature, such as changes of density, temperature, &c., or of qualities too subtle to be detected by the balance, for example amongst others, the fading of dyes, and changes in organic substances.

When either of these changes is accompanied by a change of colour, then, under conditions which are to be defined, the changes of colour can be measured, and the variations used to define quantitatively the cause of the change.

The method is founded on the fact that selective colour absorption is constant in a given substance so long as the physical and other conditions remain unchanged.

The successful use of this new power of investigation depends on the co-incidence of the following conditions :—

- 1st. A normal light.
- 2nd. A common standard of colour for reference.
- 3rd. A normal vision.
- 4th. A substance having a characteristic colour.

#### A Normal Light.

may be defined as a light made up of the six spectrum colours in equal proportions. Such a perfect light is not available under ordinary conditions, but as this class of colour work can only be carried on in daylight, we have no option but to accept daylight for the purpose. We can, however, ascertain the limits of luminous intensity, and of colour in the light, under which uniform measurements can

be made, and when the daylight is outside these limits, to a certain extent modify the excess of luminosity by a suitable shading, or collect low lights by suitable reflections. All the work hitherto done has been under these conditions, and without noticeable variations, there is as yet little reason for suspecting that diffused daylight will not meet all practical requirements.

#### A Common Standard of Colour

is found in the standard red, yellow, and blue glass colour scales which were brought under your notice two years ago.

It was then shown how, by grading the power of selective colour absorption of suitably selected coloured glass into equal units of colour equivalence, a beam of diffused daylight can be analysed into its six component colour rays, and how pigmentary colours can be measured, their colour value numerically expressed by a scientific nomenclature, and their position found on one or another of the six colour charts on the wall.

RED ORANGE CHART.

YELLOW ORANGE CHART.

YELLOW GREEN CHART.

BLUE GREEN CHART.

RED VIOLET CHART.

BLUE VIOLET CHART.

NOTE.—These charts, together with the set of colour circles, have already been before this Society, and are only inserted here for reference.

The illustration by a series of colour circles of the tri-chromatic nature of the red, yellow, and blue, together with

the monochromatic character of the orange, green, and violet standard colours.

RED GLASS.		YELLOW GLASS.		BLUE GLASS.	
Absorbs.	Transmits.	Absorbs.	Transmits.	Absorbs.	Transmits.
Yellow	Violet	Blue	Orange	Red	Green
Green	Red	Violet	Yellow	Orange	Blue
Blue	Orange	Red	Green	Yellow	Violet

Red only distinguishable.

Yellow only distinguishable.

Blue only distinguishable.

Red and yellow glass combined transmit only orange.

Blue and yellow glass combined transmit only green.

Blue and red glass combined transmit only violet.

The work of the last two years has confirmed the truth of the principles upon which the system is based, but the subdivision of the units in the colour scales has been extended. A trained vision can now differentiate the units of each scale into hundredths up to 4.

Hundredths up to 4.	
Twentieths between 1 and 6.	
Tenths	6 " 8.
Fifths	8 " 11.
Halves	11 " 20.

making 493 distinct colour sensations in a single scale of 20 units intensity.

Although there are but three colour scales to begin with, we can by their combinations of two, and of three, produce a variety of other colour scales containing, in fact, all the colours to which the vision is sensitive.

The light available this evening is the electric arc, modified by a screen to approximate the intensity of a working diffused daylight, although this light is not in accord with the normal daylight, by means of which the glasses were graded. It is sufficiently near to illustrate their power of light and colour analysis, by resolving the light into its component colours.

The first illustration is a glass standard spectrum, there are intervals of five units between the shades, whose intensities are 20 units, a continuous spectrum made by all the sensations producible by the standard glasses would be more than 92 feet long.

The whole beam is resolveable by the glasses into five groups, the variations within the groups being of degree only.

Group 1 contains the colours transmitted by a single glass standard, and is divisible into three scales.

Red contains 493 separate colour sensations.

Yellow	493	"	"
Blue	493	"	"

1479 Total colour sensations in the group.

The rays producing the colours of this group are structurally trichromatic, but visually monochromatic. The colour sensations are all chartable on the horizontal lines of their respective colour charts.

Group 2 contains the colours transmitted by two equal glass standards, which are the normals of the system in contradistinction to the standards of Group 1. It is divisible into three scales.

Orange contains 493 separate colour sensations.

Green	493	"	"
Violet	493	"	"

1479 Total colour sensations in the group.

The rays producing these sensations are monochromatic, both structurally and visually, being the only ray transmitted in common by equal pairs of standards. The colour sensations are all chartable on the perpendiculars of their respective colour charts.

Group 3. Colours transmitted by two unequal glass standards divisible into six scales.

Red Orange contains 84,424 separate colour sensations.

Yellow	84,424	"	"
Yellow Green	86,424	"	"
Blue	86,424	"	"
Blue Violet	86,424	"	"
Red	86,424	"	"

518,544 Total colour sensations in the group.

The rays producing these sensations are bichromatic both structurally and visually, and are chartable between the lines of their respective colour charts according to the proportions of the two composing colours.

Group 4 contains the light transmitted by three equal glass standards. It has but one scale, which is simply gradations of neutral gray, ranging in intensity from the smallest reduction of the original light to the black of total absorption.

The scale contains 493 separate sensations, which are structurally hexachromatic and visually colourless.

When colour is accompanied by this absorption of light the colour appears dingy in proportion to the loss of light, producing an effect similar to the mixture of pigmentary black with artists pure colours. I therefore propose to call the units of this scale "black units" when accompanied by the colour of one of the other scales.

As the charts are only constructed to define two colour sensations on any given point, the value of black units accompanying colour must be written in numerals near the colour point.

Group 5.—Colours transmitted by three unequal glass standards. This group consists of the colours of groups 1, 2, and 3, in combination with the black units of group 4.

The rays producing the sensations are either quadachromatic or quinquachromatic structurally, and may be described visually as creating two colour sensations and one light sensation.

The group contains 61,004,491 separate sensations, comprising every colour, no matter how complex, which is less pure in colour than the glass standards.

TABLE OF SEPARATE COLOUR SENSATIONS in a BEAM of NORMAL DAYLIGHT of 20 N.T. UNITS in INTENSITY.

Group 1 contains	1,479
" 2 "	1,479
" 3 "	518,544
" 4 "	93
" 5 "	61,004,496
<hr/>	
61,526,491 Total sensations.	

Large as this number is every colour has a separate numerical value, which is represented by a combination of one, two, or three of the 450 standard glasses in the box on the table, each colour can be made evident to the vision by simply viewing a normal light through the suitable combination, and has a position on one of the six colour charts.

The value of colour transmitted by a single glass is correctly indicated by the unit number it bears, but the colour transmitted by a combination of two or three glasses is not directly represented by the numbers, the colour so transmitted being the remainder after their mutual absorption.

This remainder can be obtained by means of an equation the first half of which represents the numbers on the glasses and the second half determines the colours they transmit.

For example a 1 per cent. solution of alkaline litmus in a  $\frac{1}{8}$ -in. stratum was matched by—

Standard Is.		Coloured Light transmitted.	
Red.	Blue.	Violet.	Blue.
0.90 +	8.0 =	0.9 +	7.1

This colour is a blue-violet in the proportions of the second half of the equation.

A 2-in. stratum of the same solution was matched by—

Standard Glasses.			Coloured Light transmitted.	
Red.	Blue.		Violet.	Red.
33.0 +	13.5 =		13.5 +	29.5

being a red-violet in the proportion of the second half of the equation.

The colour of crude sewage after 20 minutes standing as recorded by the curves was matched by—

Standard Glasses.			Colour of Light transmitted.		
Red.	Yellow.	Blue.	Black.	Orange.	Yellow.
8.3 +	13.7 +	6.5 =	6.5 +	1.8 +	5.4

being a yellow orange in the proportion of 5.4 yellow to 1.8 orange dulled by 6.5 black.

Another way of representing the light transmitted is to draw three parallel lines in length proportionate to the colour of glasses used, then intersect these lines at their terminals, the sections intersected will in each case represent the quality of coloured light transmitted.

These methods hold good for any combinations.

#### A Normal Vision.

The usual tests for colour-blindness do not define a normal vision sufficiently close for quantitative colour work, as without being colour blind in the usual acceptance of the term, some visions vary in their degree of perception for one or more colours.

The method adopted to measure these minor abnormal variations, was to compare the readings of a number of persons at regularly increasing densities of the same coloured liquid, then by plotting the readings of each observer into separate curves on a diagram, the ordinates of which represent the colour units, and the abscissæ the increasing density by strata thickness.

When the curves of all the observers coincide, then all the visions are considered normal, but if one deviates from the others, then the deviating vision is considered abnormal for that particular colour, the amount of deviation being in fact a quantitative test of great delicacy for degree of abnormal colour perception.

The two diagrams containing the colour curves of one per cent. solutions of alkaline and acid litmus afford an instance.

The observations were made by four independent observers, in thicknesses increasing by  $\frac{1}{8}$  in. from  $\frac{1}{8}$  in. to 2 ins.

The normal curves of the alkaline litmus chart are drawn through the coincident curves of A, B, C, and D.

#### ABSORPTION CURVE OF ALKALINE LITMUS.

1 per cent. Four observers, A, B, C, and D.

Colour Units.

observers. Tracing these curves from zero the four visions are normal for the different combinations of blue violet through the violet-blue until the blue dies out in favour of red, they continue normal for the different degrees of violet-red, and red-violet throughout the whole course of the curves.

In the acid litmus chart the orange normal is drawn through the curves of B, C, and D; A showing an increased power of perception for this colour. A is therefore considered abnormal for orange. A also deviates from the other visions in having a lesser perception for red. A is also considered abnormal for red in this combination with orange, and his observations rejected in these colours for common reference.

It will be noted that whilst the four visions are abnormal for red in the red-orange combinations of the acid chart, they coincide for red in the red-violet combinations of the alkaline chart, pointing to a kind of selective colour-blindness for red according to the colour with which it is associated.

## ABSORPTION CURVE OF ACID LITMUS.

1 per cent. Four observers, A, B, C, and D.  
our Units.

A similar divergence in the red curves of B and C occurs in this chart at the respective colour depths of 6.8 and 8.8 units, whilst from the latter point the perception of D for red slightly increases, maintaining a wide line of deviation from the others, all of which decline in a somewhat symmetrical form until they unite at the depth of  $2\frac{1}{2}$  units.

The colour changes caused by the selective colour absorption of different thicknesses of alkaline, and of acid litmus is shown by their differences of colour in the two taper vessels containing the solutions which vary from zero to 2 ins. The coloured glasses used by the four visions in constructing the curves are shown separately in bands between the taper vessels. The first band containing the glasses which produce the alkaline normal, the four bands below contain the glasses used by each separate vision for the deviations of the acid chart.

As the observations for these two charts were made for the purpose of establishing a normal of colour perception for quantitative estimations, they were carried beyond the 8 units intensity below which a vision can distinguish to  $\frac{1}{17}$  of a unit. Such divergencies as B, C, and D above this depth seldom affect their normals below.

The colour curves of all the diagrams are the normals of my own staff, possibly a wider range of observations may necessitate some slight alterations.

The possession of an abnormal vision in this modified form does not necessarily disqualify the possessor for quantitative colour work, it only means that his work is not available for common reference, he can, by constructing his own curves of vision do quantitative colour work.

The personal equation of the observer sometimes causes minor deviations which are recognised by their more or less regularly alternating on either side of the true normal,

deviations from this cause are generally too small and too evenly distributed to interfere with the plotting of the true curve.

Deviations from normal having for cause an inaccurately gauged glass vessel, or a glass standard out in colour equivalence would be self-detecting, being necessarily recurrent when the faulty vessel or glass standard is used.

## A Characteristic Colour.

All work with colours done up to the present time points to a law of selective colour absorption for definite substances as rigid as the law of specific gravity and other physical constants, but the changes of colour may be brought about either by known physical changes of condition, or by unknown conditions which are accompanied by changes of practical importance in co-relation with changes in the colour values.

In order to define the specific colour absorption of a given substance in the form of a curve, which shall be available for reference in making quantitative estimations of unknown percentages, a series of colour measurements of regularly increasing thickness are made by direct experiment. This may be effected by a separate weighing for each percentage, or, by one weighing of the smallest percentage in the series, then increasing the proportions by a regular increase in the strata thickness of the vessels in which the measurements are made.

The several percentages, together with the strata thickness of the vessels, are marked on the horizontals of the curve chart, whilst the perpendiculars are divided into the units and fractions of units of the colour equivalent scales.

The four conditions previously described as necessarily coincident for making quantitative estimations having been complied with, I now give the full detail observed in producing the lead sulphide curves.

## Lead Sulphide Absorption Curves.

The measurements for these curves were made under the supervision of Dr. Bedson, at the Durham College of Science, Newcastle-on-Tyne. The solution contained 0.25 mgrs. lead per 50 cc. of water. The curves are plotted to a scale of one colour unit per inch.

The normal is formed by the co-incident curves of three observers, and the variations in density were obtained by a regular increase in strata thickness at  $\frac{1}{2}$  in. intervals, ranging from  $\frac{1}{2}$  in. to 2 in. The results are arranged in the following table where the—

- 1st column represents the regular increase of lead by strata thickness.
- 2nd column the colours in degrees of each stratum thickness.
- 3rd column the proportion of lead denoted by each colour when measured in the  $\frac{1}{2}$  in.
- 4th column the proportion of lead denoted by each colour when measured in the 2 in.

## Lead Sulphide Percentage for Colour Table.

Colour Points of Curves.		Percentage of Lead if Measured	
Orange.	Yellow.	In a $\frac{1}{2}$ in. Stratum.	In a 2 in. Stratum.
0.14 +	0.16	0.002	0.00025
0.26 +	0.13	0.003	0.000375
0.39 +	0.14	0.004	0.0005
0.5 +	0.15	0.005	0.000625
0.63 +	0.16	0.006	0.00075
0.75 +	0.19	0.007	0.000875
0.87 +	0.24	0.008	0.001
0.99 +	0.30	0.009	0.001125

## Lead Sulphide Percentage for Colour Table—cont.

Colour Points of Curves.		Percentage of Lead if Measured	
Orange.	Yellow.	In a $\frac{1}{2}$ in. Stratum.	In a 2 in. Stratum.
1.0 +	0.35	0.010	0.00125
1.22 +	0.47	0.011	0.001375
1.35 +	0.60	0.012	0.0015
1.46 +	0.80	0.013	0.001625
1.58 +	0.82	0.014	0.00175
1.7 +	0.70	0.015	0.001875

To find the proportion of lead in a solution of lead sulphide of unknown percentages. If it contains more than 0.25 mgr. lead in 50 cc., it must be measured in the  $\frac{1}{2}$  in. cell, the proportion of lead will be found in the second column opposite the corresponding colour in the first column.

If the solution contains less than 0.25 mgr. lead in 50 cc., then it must be measured in the 2-in. cell, the proportion of lead will then be found in the third column opposite the corresponding colour in the first column.

## LEAD SULPHIDE ABSORPTION CURVE.

Colour Units.

It is obvious that having constructed the colour absorption curves for a definite compound substance, the method is applicable to a quantitative estimation of the whole compound, or to any definite part of it.

For instance, it is only necessary to supplement the percentage of lead column by percentage lead sulphide and sulphur columns to arrive at definite results in each case.

## Potassium Permanganate.

The absorption curves and resultant tables for estimating the quantity of permanganate and of oxygen consumed in an analysis were those of a solution prepared as follows:—0.395 grm. potash permanganate made up to 1 litre as a standard solution.

10 cc. of this standard solution added to 250 cc. of water and 10 cc. dilute sulphuric acid.

The curves are the mean of four normal observers.

## CURVES AND TABLES SHOWING THE QUANTITY OF POTASSIUM PERMANGANATE and of OXYGEN consumed in WATER ANALYSIS.

STANDARD SOLUTION, 0.395 grm. per litre.

Solution for curves, { 250 cc. ammonia free water,  
10 cc. dilute sulphuric acid,  
10 cc. standard solution of permanganate.

POTASSIUM FERROCYANIDE '01 PER CENT.

POTASSIUM FERROCYANIDE 1 PER CENT.

POTASSIUM BICHROMATE '001 PER CENT.

COLOUR ABSORPTION CURVES.

#### Copper Sulphate.

The variations of colour for density in these curves are too small for practical service, it would have been better measured as ammonia copper sulphate when the variations of colour for density are about six times greater. The open curve of this chart represents the degree of colour purity of copper sulphate in excess of the glass standard colours, that is, the solution was dulled by the values indicated on the curve by intercepting the light with neutral tint units.

I call attention to the curves of the 2 per cent. solutions of roasted malt marked respectively No. 7 and No. 10. The market value of No. 10 is one-third greater than No. 7. Their colour depths up to a  $\frac{3}{8}$  in. stratum practically coincide, after which the cheaper sample No. 7 becomes the darkest as having more orange, the dearer sample being characterised by an increase of yellow. This seems to suggest that depth of colour alone is not an infallible guide to fine quality in the caramels of roasted malts, and that the yellow preponderance is an important factor.

The curves of the two samples of log-wood is an illustration of measurement of dye value. The method is applicable to any kind of dyes either in the liquid or solid form.

## COPPER SULPHATE 2 PER CENT. SOLUTION.

## Colour in Water.

In the examples already given we have as bases for comparison known chemical substances quantitatively prepared by means of the balance, but in measuring the colour and turbidity in water we have not these constants for comparison, and must therefore proceed in a tentative manner in order to obtain what information the system is capable of yielding.

If the water is clear it may be measured directly for colour, and in interpreting the value of a colour, consideration must be given to the source from which the water was obtained, as, if anything approaching the yellow orange of a peat water, or the yellow-green of a river water, is found in water from gravel or chalk, it is presumptive evidence of contamination.

Mr. Parry, of Liverpool, who has used the method for some years, informs me that the first intimation of changes of condition in the water of Lake Vrynwy is sometimes given by changes of colour in the daily record of colour measurements.

## Solid Matter in Suspension.

When a water contains solid matter in suspension it must be measured both before and after filtration;\* the loss of colour by filtering represents the light obstructed by the solid matter in suspension.

The following example is that of a water supplied to Newcastle-on-Tyne during the partial water famine of last summer. The measurements were made by Mr. Pattinson (who is sanitary inspector for that city) at his laboratory:—

	Black.	Orange.	Yellow.
Colour of water before filtration	2.6 +	1.0 +	3.4
" after "	1.6 +	0.4 +	3.4
Loss of colour by filtration	1.0 +	0.6	..

It is essential to find some substance of known specific gravity, whose variations in rate of deposit by time may be recorded in terms of obstructed light. The curves formed by these variations would be available for comparison with the light obstruction curves of unknown substances.

The curves in the deposit chart represent some preliminary work in this direction. The two substances here used as possible standards are: 1st. A 1 per cent. mixture of finely-divided sulphur and water; 2nd. The deposit of carbonates in a well water after boiling. The water contained 20 grains of carbonates per gallon.

## CHART SHOWING COMPARATIVE RATES OF DEPOSIT BY TIME.

\* NOTE.—At least 10 minutes must elapse after filtering before measuring, as the act of filtering causes a temporary loss of colour.

The unknown turbid solutions are crude sewage, and a portion of the same sewage treated with 1 per cent. of milk of lime. The variations in their rates of deposit is shown by the variations of the curves on the charts.

The black curves which in the main represents the light obstructed by the solid matter are brought together in a single chart to afford a better comparison.

The remarkable changes of colour during the liberation and deposit of sulphur in a 1 per cent. solution of soda hyposulphite and dilute hydrochloric acid are illustrated by the curves on the chart: the actual glasses used are placed in a frame for examination.

#### ONE PER CENT. OF SULPHUR IN DISTILLED WATER.

Colour Units.

#### DISCUSSION.

The CHAIRMAN said that Mr. Lovibond's paper opened up a field for much further investigation. The most important point in the use of the tintometer was the permanence of its record.

They were all accustomed to more or less careful comparisons of colours, but beyond saying that one colour was like another they had no permanent record. If it were necessary to reproduce the same colour everything depended on the permanence of that selected as the standard. With these standard glasses, about whose permanence there could be very little doubt, if the same glasses were put together again, at whatever interval of time, the same colour would be obtained for comparison. He was not quite sure that he went quite all the way with Mr. Lovibond in some respects. For example, in such a case as lead sulphide the standard could be easily reproduced at any moment; a standard lead solution could be kept for an indefinite period, or could be at any time re-produced by means of the balance, and there he was not sure that the tintometer offered any great advantages. On another point he would ask for a little further information. Mr. Lovibond appeared to trust to his glasses as a means of analysing the constituent elements of a definite colour, and to say that a colour consisted of so much yellow, so much green, and so much blue, &c. But the same colour might be produced by a different arrange-

ment of constituent colours, and it was not quite fair to say because a certain colour was produced by so much green, so much blue, and so much yellow, that it contained these constituents, because one might have an exactly similar colour produced by another arrangement. Perhaps his physics might be defective and belonged rather to the old school, but he should have thought the proper way to state it was that the given colour was the colour of light of a given wave length, and that this method of mixtures was not quite scientifically accurate.

Dr. S. RIDEAL said Mr. Lovibond was to be congratulated on the progress he had made. He had now for the first time a means of standardising his glasses. In his previous papers he had never given any exact information by which glasses could be standardised in the laboratory, but by means of the diagrams he had prepared, one could ascertain whether glasses purchased from him to use with a tintometer were keeping their constant colour. Bichromate or other coloured solutions could be made up readily by means of the balance to 0.1 or 0.001 strength, and by means of the tables given in this paper chemists could ascertain whether the glasses were remaining permanent or not, since there was now on record the actual value of these glasses in ascertainable and reproducible quantities.

Mr. W. C. YOUNG said sometime back he endeavoured to apply a process of this kind to the determination of the organic matter in water, and for a time it seemed very promising. His experiments were confined to river water, and the standard was one made by a definite quantity of ammonium salt coloured by Nessler's solution. One litre of water was concentrated to 5 cc., all earthy matter was precipitated by sodium carbonate, filtered away, and a clear solution of 5 cc. volume remained. This did very well with river waters, but when he came to apply it to deep well waters, whether from the chalk or the new red sandstone, he found the organic matter in the water gave quite a different colour value, and consequently the method had to be abandoned. He might say also, that the organic matter in moorland water had a deeper colour for a given quantity than either river water or deep well waters.

Mr. D. HOWARD said the old certainty that there were three primary colours which, combined together, made all the others, had now disappeared, and if he might judge from the recent results which Captain Abney had given, it appeared that various combinations might make the same colour. At the same time there was this practical residue of knowledge left, that a definite record of a given colour was a very valuable thing to us, but it could not be too strongly impressed on all those who dealt with colours as a means of quantitative analysis, that the circumstances must be the same. The example which had been mentioned, which was a very admirable one, of the enormous difference which the presence of organic matter made in the colour of sulphide of lead precipitated under otherwise similar circumstances, was only one of those cases which occurred in all study of these matters. Other things therefore being equal, a constant record of colour was of the greatest possible importance, and, as far as he could judge, Mr. Lovibond had given in these glasses a better standard than any other which had been yet made. It must nevertheless be borne in mind that the personal equation came in with tremendous effect. There was not only that remarkable phenomenon colour blindness to be taken account of, but there was the fact that the sensitiveness to shade was extremely imperfectly developed in a great many eyes; and only those could speak with certainty of their judgment on a shade of colour who had trained their eyes, and proved that the training had been of any use. If an untrained person said the two colours were identical it was information of very little value. These two points seemed to be of prime importance—that the circumstances under which the colours were produced must be exactly identical, and that the personal equation must be carefully sought for and guarded against.

Dr. KOHN, Hon. Secretary of the Liverpool Section, said he had had some little experience in dealing with

the determination of lead by colour tests, and he would remind them that in a paper by Mr. Warrington, on the detection of lead in citric and tartaric acids, it was pointed out that a great deal depended on the constituents in the solution, and this would bear out the differences in the results mentioned by Mr. Young. In testing for lead in the presence of citric or tartaric acid, the deficiency of the colour test was immensely greater than with aqueous solutions. That was to his mind the great difficulty in applying the colorimetric tests in the laboratory, for they depended entirely on the conditions of the experiments. He would ask Mr. Lovibond whether, in the table for lead sulphide, which was undoubtedly most useful to anyone using a pure solution of lead, he had made similar tests in the presence of salts of any kind, and if so, what the influence of those salts had been on the colour values.

Mr. E. J. BRYAN said he could confirm what Dr. Kohn had said about the sensitiveness to colour of lead sulphide in the presence of tartaric acid or citric acid. Some time ago he had to determine small quantities of lead in mineral waters, and he found the effects were much increased by the addition of sugar to the solution. The intensity of the black colour due to the lead sulphide was increased about 10 times with the same quantity of lead present.

Mr. BRYAN CONGERY said the advance which Mr. Lovibond had made in this subject was very great, but one of the chief difficulties he found was the question of daylight, and he should like very much to know if Mr. Lovibond had succeeded in making or finding an artificial standard of light to work by.

Mr. BOVERTON REDWOOD said, hitherto the criticisms on this paper, though valuable, had been mainly of a destructive character, but he desired to give expression to his recognition of the importance which attached to the self-denying labours of Mr. Lovibond. This was not the first occasion on which he had taken upon himself to speak in somewhat eulogistic terms of the practical value of the instruments Mr. Lovibond had placed at their disposal. He had had undoubtedly to contend with great difficulties, and it might be that even greater difficulties lay ahead, but those who had followed the work he had done must have been impressed with the painstaking manner in which he had devoted himself to the subject, and there was good reason to hope that, on further investigation, all the points which had been raised would be satisfactorily dealt with; they certainly owed him a cordial vote of thanks, not merely for his paper, but for his labours in connection with this subject, which had now extended over many years. It was longer ago than he cared to remember since Mr. Lovibond first brought him the tintometer, and asked him whether it would be a useful instrument to employ in recording the colour of oils. Since that time it had been in constant use in his laboratory, and they would be sorry to be without it, for it was found to be of great utility.

Mr. B. E. R. NEWLANDS said he was himself quite a disciple of Mr. Lovibond. He believed he possessed the first instrument which had been sent to London, and this had been continuously used ever since. It was easy to criticise this tintometer, and to say that because it only gave an arbitrary standard of colour, and not one constructed on a purely scientific basis, it was of little or no use. He failed to see that entirely, and thought it was of slight importance whether the standard chosen was a scientific or an arbitrary one, so long as it was uniform and unalterable.

Mr. Lovibond had selected a material, viz., glass, which was a most permanent one to make a standard of; and, after spending an enormous amount of time in carefully graduating the colours of various glasses, he had introduced a standard which could be thoroughly relied upon so far as it went. He had much pleasure in seconding the vote of thanks to Mr. Lovibond for the labour he had undertaken, more especially as he was well aware that his work in connection with this invention was not so much with the idea of pecuniary profit as of rendering an important service to his fellow-men.

Mr. E. J. BRAY asked if Mr. Lovibond included in his scheme any method for the determination of ammonia in drinking water so as to compare with Nessler's solution?

Mr. J. W. DINHAM, speaking as a visitor, and connected with the grain trade, had great pleasure in supporting the vote of thanks. Chemistry had gone a great way to analyse grain, particularly barley and wheat, but in the matter of wheat, buyers in Mark Lane went on the question of colour in order to estimate the quality and quantity of gluten. The amount of soluble and insoluble gluten in the grain was important to millers, and the value of that was determined by the colour. Until they had a standard of colour in testing wheaten flour they could not recognise one sample from another, because of the bleaching qualities of the flour if kept as a standard sample. Mr. Lovibond had brought before them the means of estimating the colour, by standard glasses which were constant. It was a constant colour that they required in estimating value of breadstuffs, as colour indicated the development of the tissue of the grain and the quality of the insoluble gluten. They were able by this means to ascertain the quality of the grain, and to estimate the value of the flour manufactured from it.

Mr. E. F. HOOPER asked Mr. Lovibond whether in his investigations on this tintometer he was able to give any idea of the colour value of fluorescent bodies. Those who come in contact with oils would be very glad if they could fix on definite colours.

Mr. J. W. LOVIBOND, in reply, said in reference to the Chairman's suggestion that a colour might be produced in several different ways, he should say emphatically under daylight conditions it could not. As to what might be done by mixing the light of the various parts of the spectrum, his experience was too small to be of any weight, although he had never seen satisfactory results in any lecture he had attended, but with daylight the slightest variation of a single ray altered the colour. The set of glasses were so graded that they defined the slightest alteration, whether in the whole light or a part, and you could not disturb the constituents in any way without disturbing the visual sensation. He had had very little experience with regard to aqueous solutions; he had simply worked out the method of measuring the colour, and could only say that it recorded the slightest change of colour, and he had no hesitation in saying that, if there were a variation in a colour due to different properties of organic matter, the curve of absorption for the variation would show the difference, and in that way the method would be of very great value for estimating the qualities of water. It had yet to be worked out, however, and he had done nothing in that direction, except the instances given. The whole system of curves had been evolved since he gave notice of this paper, which was to have been on very different lines, and it would be seen that very little critical work could have been done except in the examples given. With reference to the influence of salts on lead sulphide, he could only go by analogy, but he should say that so long as the salts were colourless the influence would be nil, but the instant a coloured salt intervened then the system was useless. The colour of the foreign body, whatever it might be, must be eliminated before satisfactory results could be obtained. With reference to the simplicity of the yellow, and its being produced in various ways, these glasses would record the slightest change. No yellow varying from another yellow could be recorded by the same glass. The sodium line he did not regard as a pure yellow. He regarded it as a yellow orange, and any departure from that must be made evident by the glass on observation. Five minutes would convince anyone of the truth of this. The personal equation he granted was an important element, but it was one which could be measured and must be settled before uniform work for reference could be done. The curves in the acid litmus chart defined how near they could go towards settling it; these curves were formed by individuals without any communication with each other. As he pointed out in the alkaline litmus chart, the four coincided in the comparison of records after they were independently made. In the acid chart they varied to the extent shown, that is to say, they coincided at the beginning and at the finish with

one exception. Such a record would be necessary before any work for publication could be done. He believed it would be found that the variation from colour blindness was not so great as was frequently supposed. The personal equation was simply a matter of observation, and, like the balance, you might let it sway a little on one side or the other, but when you had a collection of vibrations on the two sides they balanced each other if it were simply a matter of personal equation. The question of artificial light was a difficult one to deal with, and from his experience he should say it was impossible to do critical colour work with any artificial light. In the first place the rays from artificial light were not in the same condition as diffused daylight. One got a different kind of energy in the intense direct rays from artificial light to what one did from the diffused light after it had been reflected and selectively absorbed backwards and forwards an innumerable number of times. It was quite possible that an artificial light might be made to do some simple kinds of colour work, but one would either have to regrade the present, or to make a separate set of glasses, and to find a different material for colouring them, because the cobalt of blue was peculiarly susceptible to the penetrative character of the red ray of artificial lights. This red ray seemed to have a property of penetration apart from its colour value, which can be neutralised by reflection. In fact, the work done by means of these glasses was quite different to that done by intense light through lenses and after reflection from mirrors. With reference to the value of this method for quantitative work, given the four coincident conditions defined in the paper, whatever the balance could do he could without hesitation pronounce to the millionth of 1 per cent. by this system for lead sulphide evolved under the direction of Dr. Bedson. He had no doubt it could be made available for estimating ammonia in water very rapidly. The first method for this purpose was by means of arbitrary glasses, and that was the one now mostly used in laboratories, where the system was adopted more than 25 years ago, but under the colour equivalent system, some little work would have to be expended upon it, and as he had but one pair of eyes he thought he might fairly ask some of the younger men to undertake such work. For oils it was in constant use, and he was fortunate in having the testimony of Mr. Redwood to its value, but as a matter of fact it was rapidly coming into general use for this purpose, and he thought its utility might be enlarged even to differentiating between the sources of oils. He had no doubt that oils from different sources would show different absorption curves; at any rate if the colouring properties were different this would be so, and when they were similar the curves probably would be similar. In conclusion he thanked the Society for the kind manner in which his paper had been received.

## THE NATURAL DIMINUTION OF THE DISSOLVED ORGANIC MATTER IN THE WATER OF RIVERS.

BY W. C. YOUNG, F.I.C., F.C.S.

*Consulting Chemist to the Lee Conservancy.*

THERE is a wide difference of opinion amongst chemists who have devoted attention to the subject, as to whether the organic matter in solution in the water of a river is diminished by the operation of natural processes during its flow. Some authorities hold that the diminution, from any cause, is extremely minute, whilst others contend that natural oxidation destroys the bulk of the organic matter in solution in the course of a few miles' flow.

Dr. P. Frankland, in a paper on the "Self-Purification of Rivers," read before the Congress of Hygiene, held in London in August 1891, states, as a result of experiments he had made upon the Thames and other rivers, that there was practically no loss of organic matter in solution during the flow of a river. He states, as his opinion, that the

improved appearance of a river, which is always noticeable some distance below the spot at which it receives pollution by sewage, is due to sedimentation, and that oxidation has little or no influence in the improvement. I presume he means by this that the matters in suspension have been deposited on the bed of the river, and that the improvement consists merely in the water having become clearer and brighter.

Perhaps the most marked features in a sewage-polluted stream are its inky colour and offensive odour, the former due to iron sulphide and the latter to sulphuretted hydrogen. There can be no doubt that to a very great extent these are oxidised, and the improvement in colour and odour may therefore be attributed to oxidation alone.

In the spring of 1891 and again in 1892, I had occasion to make a series of analyses of samples of water from the River Lee from its source, above and below each tributary,

down to the intake of the East London Waterworks Company at Ponder's End. The investigations were originally made for the purpose of ascertaining what effect the mixture of water from the tributary streams had upon the composition of the water in the main river but the results also show the variation in the amount of dissolved organic matter in the water after flowing a considerable distance, and should throw some light upon the "oxidation" question. The samples, on each occasion, were taken under the most favourable circumstances, the weather having been fine and dry for two or three weeks previously, so that surface water was entirely absent from the streams and the water therefore in its normal condition. The total dissolved organic matter in each sample was determined by the process described in my paper read before the Society in November 1891.

The results are stated in the following table:—

TABLE No. 1.  
Grains per Gallon.

No.	Source of Sample.	Distance from Point above.	Date.	Total Dissolved Organic Matter.	Date.	Total Dissolved Organic Matter.
1	Source of River Lee.....	—	1891, 14 April	0.511	1892, 6 April	0.569
2	100 yards above River Murrum .....	23 miles	"	0.633	"	0.420
3	" " Beane .....	1 "	21 April	0.672	7 "	0.329
4	Intake, New River Company .....	1 "	"	0.441	"	0.308
5	100 yards above River Ash .....	3 "	"	0.529	8 "	0.497
6	" " Stort .....	1 "	"	0.623	"	0.394
7	100 yards below Waltham Abbey Sewage Farm.	6½ "	"	0.685	9 "	0.490
8	100 yards below Small Arms Factory Sewage Farm.	1½ "	"	0.490	"	0.418
9	Intake, East London Water Company, Ponder's End.	2½ "	"	0.483	"	0.385

The results show, especially in the 1892 samples, that the river, when free from flood water, contains very little organic matter in solution. In the 1891 samples the maximum amount was found in No. 2 (100 yards above the junction with the Murrum), and the minimum in No. 4 (the intake of the New River Company), the difference being 0.252 grain. This diminution appears to be due to the admixture of the water of the River Beane (which joins the Lee between these two points) with the main river, as samples taken at the same time from the Beane and 100 yards below its junction with the Lee, gave 0.252 and 0.469 grain dissolved organic matter per gallon respectively. In the 1892 samples the maximum found was in No. 1 (taken at the source of the River Lee), and the minimum in No. 4 (the intake of the New River Company), the difference being 0.252 grain, the same as in the 1891 samples.

As it is evident that the river receives small additions of organic matter at various points in its course, and is undoubtedly diluted occasionally by spring and river water of greater purity than its own, it is almost impossible to draw any definite conclusion as to the rate at which the dissolved organic matter diminishes, but it is evident, from these results, that there is a tendency toward diminution, although the action appears to be very slow.

I may here mention that the natural spring water in this locality contains an appreciable quantity of dissolved organic matter, the samples from the springs at the source of the Lee in Leagrave Marshes, Bedfordshire, giving rather more than  $\frac{1}{2}$  grain per gallon, and samples taken in April 1891 and 1892 from Chadwell Spring, the New River Head, giving 0.693 and 0.42 grain per gallon respectively; therefore such water mixing with the main river can have but little effect in lessening the proportion of dissolved organic matter.

After the water passes Keid's Weir, Ponder's End, which is the intake of the East London Water Company, there is absolutely no chance of increase of dissolved organic matter

by the addition of polluted water, or of decrease of organic matter by dilution with purer water, so that from this point to the time it reaches the consumer it is exposed to the action of natural processes, and a comparison of the results obtained from the water taken from the East London Water Company's mains with those from the water at the intake, would show the degree of purification effected in this way.

I am informed by the engineer to the East London Water Company that a period of from 18 to 21 days would elapse before the water which has passed Keid's Weir would be delivered at the offices of the Board of Works for the Poplar District, where my laboratory is situated. Accordingly, in order to obtain results fairly comparable with those given by the sample taken at Keid's Weir on April 9, 1892 (No. 9, Table I.), which contained 0.385 grain per gallon, I determined the total dissolved organic matter in the water supplied to my laboratory (taken direct from the main) daily from the 26th April to the 5th May 1892.

The results are given in the following table:—

TABLE No. 11.  
Grains per Gallon.

No.	Total Dissolved Organic Matter.
No. 1 .....	0.28
" 2 .....	0.21
" 3 .....	0.21
" 4 .....	0.21
" 5 .....	0.308
" 6 .....	0.21
" 7 .....	0.371
" 8 .....	0.28
" 9 .....	0.3
Mean .....	0.264

Taking the mean of these results, and comparing it with the 1892 sample from the Water Company's intake, it will

be seen that after the water has travelled a distance of four miles to the reservoirs, been exposed to the air in the reservoirs for about 20 days, flown thence one mile through an open stream to the filters, and passed through about six miles of mains, the organic matter is reduced from 0.385 to 0.261 grain per gallon, or 31 per cent.

These experiments having been made upon water containing only a very minute proportion of dissolved organic matter, I thought it desirable to extend the investigation to highly polluted water, such as sewage effluents, in order to ascertain whether the rate of decrease of dissolved organic matter was the same or not. Accordingly two samples of such water, which had been standing in stoppered bottles in my laboratory for about six months, were placed in open vessels, covered with paper to exclude dust, and frequently shaken so as to renew the supply of dissolved oxygen. At the commencement sample No. 1 contained 4.9 and No. 2 3.6 grains dissolved organic matter per gallon. After 14 days a bright green microscopic growth developed in No. 1, which rapidly increased in amount until, after 42 days, the water was of an intense green colour. It was then filtered through asbestos, the finest filter-paper being useless for the purpose, and the dissolved organic matter determined. This was found to have dropped to 1.7 grains per gallon. The filtered water was again set aside, frequently agitated, and after a further period of 30 days (during which a slight additional growth developed) was found to contain 1.1 grains per gallon.

In the case of sample No. 2, which at the commencement contained 3.6 grains dissolved organic matter per gallon, only a faint appearance of green colour was observed after 42 days, and the organic matter in solution then amounted to 3.5 grains per gallon, or practically the same as at the commencement. Shortly after, the green growth developed rapidly and in the course of week amounted to nearly as much as in No. 1. After a further period of 30 days the dissolved organic matter had fallen to 2.2 grains per gallon.

The results of these experiments are very interesting, and show clearly that oxidation has little, if any, influence in removing the dissolved organic matter. In both experiments the water was well shaken three or four times every day for a period of six weeks, and in No. 2 there had been practically no diminution. In No. 1, after two weeks, a vigorous growth of microscopic vegetation had commenced, and after six weeks (when the growth appeared to have reached its maximum) the organic matter was found to have dropped from 4.9 to 1.7 grains per gallon. After a further period of 30 days (the green growth having been previously separated) during which the water was well shaken every day as before, a very slight additional growth occurred and the organic matter amounted to 1.1 grains per gallon. In No. 2 oxidation had no effect after six weeks, but the growth of vegetation brought down the organic matter from 3.5 to 2.2 grains per gallon in four weeks.

Having a number of samples of originally very foul sewage effluents which had been filtered and set aside for a very long period in stoppered bottles nearly filled, I thought it would be interesting to know whether any alteration in the quantity of dissolved organic matter present had taken place. In all the samples the dissolved organic matter originally present was known, and in two the amount contained after keeping a few weeks had also been ascertained. The dissolved organic matter in each was therefore determined, the results obtained being stated in the following table:—

TABLE No. III.

DISSOLVED ORGANIC MATTER IN SAMPLES OF SEWAGE EFFLUENT.

Grains per Gallon.

	1.	2.	3.	4.
At startline .....	13.6	24.0	9.6	15.7
After 6 weeks .....	..	..	..	3.8
" 7 " .....	..	..	3.0	..
" 18 months .....	5.6	4.5	2.7	3.1

These samples had all been kept in a badly lighted place, and the bottles being nearly full, and never opened except for the purposes of these experiments, it is evident that atmospheric oxidation had taken no part in the reduction of the organic matter. In each case, however, a considerable growth of fungus had developed; therefore, there can be little doubt that it was to this that the purification was due.

As it seemed probable that the organic matter represented by the fungus would account for the amount abstracted from the samples, I collected the insoluble matter from each sample and determined its amount. After deducting the ash the quantity in each sample was as follows:—

Grains per Gallon.

1.	2.	3.	4.
0.4	2.1	1.1	2.5

It is evident from these results that the lost organic matter cannot be accounted for in this way, but the experiments were necessarily very rough and far from conclusive, as it was impossible to remove the whole of the deposit from the bottom and sides of the bottles. Sewage fungus is also extremely unstable, decomposes rapidly on exposure to the air, and when disturbed has the property, apparently, of returning to the water much of the organic matter it has previously absorbed from it. In illustration of this latter property, I may mention an experiment I made some years ago. A quantity of fresh sewage fungus, after draining, was immersed in distilled water, shaken, and set aside over night. In the morning the whole was thrown on to a filter. The filtrate, which was of a greenish-yellow colour and had a most offensive odour exactly resembling rotten green vegetables, was acid, and slowly deposited a reddish-brown precipitate, which contained ferric oxide. After the filtrate had ceased to deposit the brown matter above referred to, the clear liquid was analysed with the following result:—

	Grains per Gallon.
Total solid residue dried at 220° F.....	149.0
Loss on ignition .....	65.0
Chlorine as chlorides .....	7.0
Free ammonia .....	22.34
Albuminoid ammonia .....	0.647
Organic carbon.....	13.58
" nitrogen.....	27.16

The albuminoid ammonia and the organic carbon and nitrogen results are all undoubtedly too low, as it was evident by the strong odour given off during the distillation and evaporation respectively that a considerable quantity of volatile organic matter was lost. I regret that, at the time this experiment was made, my method of determining the organic matter in solution was not devised, as it would have been extremely useful.

These results afford conclusive evidence that sewage fungus, when disturbed or on decomposition, gives up to the water in which it is immersed a large proportion of soluble organic matter and also much soluble inorganic matter; in fact, such water upon being subjected to the usual course of analysis gives every indication of sewage pollution.

With a view to ascertaining the effect produced upon the amount of soluble organic matter in crude sewage by the growth of sewage fungus, I took two portions of crude sewage, which contained 17.5 grains of dissolved organic matter per gallon; to one I added 7 grains and to the other 14 grains of sulphate of alumina per gallon. After vigorous shaking, the liquids were set aside for four hours, by which time the suspended matter had completely subsided, leaving a clear liquid above. The clear liquid was then siphoned off, and the dissolved organic matter determined in each. The result showed 15.6 grains per gallon in that to which 7 grains of sulphate of alumina had been added, and 13.5 grains per gallon in the other, where 14 grains of sulphate of alumina had been employed.

I may remark, in passing, that this experiment shows that hydrate of alumina precipitated from sulphate does not possess, to any appreciable extent, the property so often claimed for it of uniting with the dissolved organic matter in sewage and so rendering it insoluble; and further, as I shall subsequently show, does not prevent the growth of sewage fungus in the clarified liquid.

The clear sewage waters obtained as above described were then set aside in open vessels, covered to exclude dust. After three days, during which the water became increasingly turbid, a growth of fungus commenced on the surface, ultimately completely covering it. In the course of a few days it had extended from beneath, in long filaments and festoons, nearly to the bottom of the vessel. After three weeks the fungus became detached from the surface of the water, fell to the bottom, and gave slight signs of decomposition. The clear liquid was then siphoned off, care being taken not to disturb the fungus, and the dissolved organic matter determined in each. The result showed 6·8 grains per gallon in No. 1 and 4·6 grains per gallon in No. 2.

The fungus at this stage was collected and weighed. After deducting the ash, the amount found was equal to 2·5 grains of organic matter per gallon in each case.

The clear liquids were then set aside in open vessels for a further period of five weeks and frequently shaken every day. During this period a minute quantity of a colourless microscopic growth consisting of simple cells developed, but there was no further appearance of fungus, and at the end a green growth commenced similar in every respect to that already referred to. The dissolved organic matter was then determined and amounted to 5·1 grains per gallon in No. 1 and 3·9 grains per gallon in No. 2.

These results prove conclusively that the development of sewage fungus has a remarkable effect in removing dissolved organic matter from sewage water, as in the case of Experiment No. 1, 57 per cent., and in Experiment No. 2, 66 per cent., was removed by its agency in three weeks. They also confirm the results of experiments previously alluded to as regards the effect of atmospheric oxidation, as, assuming that the whole of the loss was due to that cause (which is extremely doubtful), in the case of Experiment No. 1 only 25 per cent., and in Experiment No. 2 only 15 per cent., of the dissolved organic matter was removed in five weeks.

The results of these analyses and experiments compel me to come to the following conclusions, viz. :—

1st. The removal of dissolved organic matter from river water by natural means is extremely slow.

2nd. The principal agent in the removal of dissolved organic matter from river water is the growth of vegetation.

And 3rd. That atmospheric oxidation has little or no effect in removing dissolved organic matter from river water.

#### DISCUSSION.

The CHAIRMAN said this paper was extremely interesting, and was evidently the result of a very large amount of careful and patient work. The question of the removal of organic matter was very complicated and perplexing. It seemed quite evident that a polluted water might contain a quantity of dissolved oxygen in contact with and abundantly sufficient to completely destroy all the organic matter for an almost indefinite period without any change whatever taking place. If that water were filtered or passed through or over any very large surface, such as sand, decomposition was set up, and the organic matter was destroyed. It was a matter rather for question whether even the action of this kind of fungus in the water was not possibly in some way one of surface.

Mr. D. HOWARD said he never could quite fall in with the view of those who maintained that no length of time in a river could remove any organic matter from it, because it was the case where did the water-cresses come from. This was putting the matter crudely, but the life history of water-cresses threw some light on that of organisms much

smaller than water-cresses and of greater importance. Those who knew the New River from Bedfordshire down to London would know that there were vast beds of water-cress; the best were not on the Lee, but on tributaries in which there were certain elements which were well kept out of the Lee by the water-cress. It was self-evident that these water-cresses came from somewhere, and if they were taken away there was so much less organic matter in the water; if they were not picked they decayed and went back again into solution like the sewage fungus. He remembered a very hot discussion in that room on one occasion, whether it was possible for oxygen and shaking to remove organic matter from water, and it was fairly proved that it was not, but the question which the development of modern study now naturally suggests as to the action of organic life was left out of consideration. Even the mere question of filters was complicated by possible organisms on the filters. He remembered reading a foreign investigation on the effects of filtration, which certainly appeared to show that there were organisms attaching to the grains of sand which had a good deal to do with the purification of water by filtration. There was one question that he should like to ask with regard to the extent of pollution. He was under the impression that a good deal of chalk water was pumped in below Ponder's End lock, between there and the filter beds at Chingford Mills, and he should like to know if that were so.

Dr. DARRÉ thought by this time everybody had agreed that direct oxidation had nothing to do with the purification of a river. It was entirely due to organisms; under which term he, of course, understood all living things, vegetable or animal, microscopic or otherwise, to be included. When he first stated that proposition eight or ten years ago he was laughed at, but he was certainly under the impression that it was now entirely accepted, for sterilised water had no power of oxidation, but if they allowed life to exist it oxidised considerably. The River Thames gave a splendid example of immense pollution and corresponding purification. During the Royal Commission of 1883, Mr. Latham calculated that there was between Barking and Greenhithe as much as 17 days' London sewage in the river. The river was at that time frequently analysed, and it was possible to calculate the actual amount of sewage in it; this was less than two days; in other words, nearly nine-tenths of the sewage discharged into it had been destroyed between Barking and Greenhithe. About that time he and others analysed the water hundreds of times, and to his great astonishment he found that the river was always purer in summer than in winter, although it looked fouler there was less organic matter, simply because there was more life in the warm summer than in winter. In winter there was much more fresh water in the river, and only the same amount of sewage, and the river ought therefore to be purer in winter than in summer, but the reverse was the case. Thus in January, March, and May 1892 the average composition of the river between Greenwich and Erith at high water in terms of albuminoid ammonia was 0·030 grain per gallon; at low water, 0·025; the mean being 0·027. In July, August, and September it had sunk to a mean of 0·021. The oxygen absorbed, taking the mean of 100 or 200 analyses, was 0·216 in the cold months, 0·18 in the warmer months, again showing that, measured by the oxygen absorbed, the river was purer in summer than in winter. There could not be any doubt now that the purification was entirely due to the action of organisms, but it depended on the kind and number of organisms. One might make hundreds of experiments, but unless one knew the number and nature of the organisms present they were valueless. Temperature also was of importance, as warmth favoured the growth of organisms. There was an immense amount of purification constantly going on in the River Thames, otherwise it would really be in the horrible condition in which fancy painted it sometimes; but, in fact, notwithstanding the enormous amount of sewage discharged into it, the river was practically pure 10 or so miles lower down.

Mr. W. C. YOUNG, in reply, said the chalk well-water about which Mr. Howard asked was not pumped into the river,

but direct into the local mains, and did not reach the reservoirs at all. With regard to Dr. Dupré's remarks, he must say that he did not think any investigation had been made on the lines on which he had made these. All other investigations had figures obtained by the albuminoid process, or by Frankland's organic carbon and nitrogen process; these figures did not represent definite amounts of organic matter. He thought he should be able to show that that organic matter contained varying proportions of carbon, and therefore by Frankland's method they would not get so reliable a result as working in the manner he had done. He quite agreed with Dr. Dupré that the condition of the river water was, as regards the quantity of dissolved organic matter, worse in the winter than in the summer, although it might appear to be better. The water supplied by the East London Waterworks Company contained a little over 1 grain of organic matter per gallon last month, whereas in the summer it dropped to below 0.2 of a grain. He did not think Dr. Dupré had given sufficient credit to vegetation, or rather had made no distinction between vegetation and the action of bacteria in removing the dissolved organic matter. The experiments recorded in the paper, especially those in which a bright green algae developed, showed clearly that vegetation was a very potent power in removing dissolved organic matter. Many experiments had been made which tended to show that crude sewage contained no organisms or microbes whatever; that there was something there which killed them. Dr. Percy Frankland showed, in a paper read some years ago, that by precipitating alumina in water containing an enormous number of microbes, he practically sterilised it. In these experiments that had been done, and the crude sewage matter after clarification, he presumed, would contain no bacteria. It contained certainly 9 to 15 grains of organic matter per gallon, and that was almost entirely removed by the growth of sewage fungi and the subsequent growth of vegetable matter.

The CHAIRMAN said that Mr. Young's remarks on Mr. Lovibond's paper made him think of the evidence there given, that the organic matter in water was of very varying character. If a way could be found of ascertaining, not only how much was present, but what it was, it would add very greatly to their knowledge. Whether they attempted to determine the total weight of organic matter, or of carbon in it, or of albuminoid ammonia obtained from it, the question of the variability of its nature remained.

#### NOTE ON AN IMPROVED SPECIFIC GRAVITY BOTTLE.

BY HENRY LOUIS, A.R.S.M., F.I.C., F.G.S., M.A.I.M.E., ETC.

DURING the course of an investigation which necessitated the determination of the specific gravities of a series of pulverulent substances of high density, I found that the ordinary type of bottle was in so far defective that it is impossible to determine its weight, when filled with water under ordinary circumstances, with absolute accuracy. It is obvious that any errors in this weighing will affect the determination of the specific gravities of very heavy substances proportionately more than in the case of comparatively light bodies.

I found that the irregular results are due to the very rapid evaporation that took place from the capillary tube within the atmosphere of the balance case when this was, as usual, kept dry by means of a vessel containing sulphuric acid or calcium chloride; even when the latter was withdrawn and a beaker of water substituted, the evaporation, although it diminished, by no means ceased.

It would seem that the excessively thin film of water, which forms the margin of the meniscus in the capillary tube through the stopper, evaporates very rapidly, and that this evaporation is supported by the capillary action of the

tube until the latter is entirely emptied. The action appears to be independent of small variations of temperature.

Thus in one experiment, the full bottle, the approximate weight of which was known, was weighed as rapidly as possible, and then again after successive intervals of time, the temperature being recorded at the same time.

The results are here given in tabular form:—

	Grains.	Temperature.
		° C.
1. First weighing .....	1328.000	16.9
2. After 5 minutes .....	1328.940	16.9
3. " 20 " .....	1328.899	17.0
4. " 30 " .....	1328.850	17.1
5. " 45 " .....	1328.795	17.4
6. " 60 " .....	1328.755	17.6

These results are also shown graphically in the annexed diagram, Fig. 1, from which it will be seen that the rate of loss, after the first five minutes, is practically uniform.

Fig. 1.

Fig. 2.

IMPROVED SPECIFIC GRAVITY BOTTLE.

In the course of an hour the loss amounted to 0.245 grains, the level of the meniscus in the capillary tube

having been meanwhile lowered to the extent of 0.65 in. It is quite evident that such considerable loss of weight cannot be neglected in accurate experiments, seeing how much time an accurate weighing takes; in fact the loss of weight is so rapid that it is scarcely possible to weigh the bottle exactly at all on a sensitive balance.

In order to do away with this source of error, I have had a specific gravity bottle made, which differs from the ordinary type only in that the stopper is longer than usual and is graduated, whilst a light glass cap is ground to fit accurately over the neck of the bottle, as shown in the accompanying figure (Fig. 2).

The bottle is filled in the usual way; the neck and stopper are then rapidly wiped dry, the cap put on, and the body of the bottle then dried. When weighing the bottle, any variation in the height of the column of fluid in the capillary tube must be read off on the graduations, which may be to any convenient scale; mine are  $\frac{1}{10}$  in. apart, corresponding to 0.01 grains of water. It is an easy matter to calibrate this tube and thus to apply the necessary corrections. The capped bottle can be left for any length of time without any loss of weight taking place. I have noticed, however, that, after standing for 21 hours, considerable evaporation had taken place from the capillary tube, the water being condensed in comparatively large drops on the inner surface of the glass cap. This does not matter, provided that the temperature of the water and the level of the meniscus are read at once as soon as the bottle is ready for weighing; the weighing itself can be performed at any time thereafter.

and each succeeding one less of the nitric acid, until from the overflow of the last one the bisulphate of soda flows away without any nitric acid.

I may point out that while the ordinary process of making nitric acid is one of fractional distillation by time, mine is fractional distillation by space.

Instead of the operation being always at the same point of space, but differing by the successive points of time, I arrange for the differences to take place at different points of space, and these differences exist during one and the same points of time.

Experience has shown that there may be considerable variation made both in the proportion of sulphuric acid used and also in its strength, enabling one to obtain the nitric acid from the different still-heads of varying strengths and varying proportions of acid of these varying densities. This is useful to those makers who require different acids for differing trade purposes.

It is also quite possible to produce the full product of nitric acid of the full gravity of 1.500.

With regard to the saving effected by my system, it has been found to exceed my expectations.

I now save more than two-thirds in fuel, also save four-fifths of the condensing plant.

## NOTE ON AN APPARATUS FOR THE CONTINUOUS PRODUCTION OF NITRIC ACID.

BY MAXWELL PRENTICE.

By the kind invitation of the Committee I have the honour to exhibit a model of the apparatus designed to produce nitric acid in a continuous manner.

As long ago as 1878 I carried to a very satisfactory issue experiments in the continuous distillation or rectification of sulphuric acid. The system of platinum pans which I invented was soon adopted by the largest makers of oil of vitriol, both in Europe and America, and the Prentice pan holds its own, in my opinion, to this day.

The great saving in fuel and general convenience of a continuous process is now so well recognised that you will not be surprised to learn that soon after patenting my platinum pans for the concentration of sulphuric acid, I began experiments with the object of discovering some method by which nitric acid could be produced without the loss caused by the alternate heating and cooling which occur in the ordinary process.

The difficulties seemed, however, insurmountable, and it was not until 1892 that I again took up this question, and discovered important points which enabled me at last to solve the problem.

The model before you is a very exact copy of the apparatus which has been working satisfactorily at Stowmarket for some time.

The nitrate of soda is placed in weighed quantities into the hopper, whence it passes (in the same manner as grain runs in a flour mill) to the feeder. This feeder is a miniature horizontal pug-mill, which receives the streams of acid and of nitrate, and after thoroughly mixing them delivers them into the still, where, under the influence of heat, they rapidly become a homogeneous liquid, from which nitric acid continuously distils.

The still is divided into compartments or chambers in such a manner that the fluid may pass continuously from one to another. The nitric acid being continuously separated by distillation, the contents of each division vary—the first containing the full proportion of nitric acid

One of my stills, capable of producing about four tons of nitric acid per week, weighs less than two tons; whereas (to produce the same quantity) two stills weighing five tons each were formerly used.

This saving of four-fifths of the weight of iron is accompanied by a corresponding saving in the cost of masonry.

There is also reason to believe that the life of my new still will be 10 times greater than that of any previous still, for the destruction of the stills has been due to the alternate heating and cooling, with the consequent condensation of acid vapours within the still. This is, of course, entirely obviated by my continuous process.

I hope that my work in improving the process of production of nitric acid may be as useful to the makers of nitric acid as my improvements in the production of oil of vitriol have been to the makers of sulphuric acid.

#### DISCUSSION.

MR. T. TYLER asked what was the relative life of the body of the still and the cast-iron top, and what was the minimum strength of acid Mr. Prentice found possible to use with the nitrate in order to secure sufficient fluidity for the outflow sulphate of soda with the smallest possible excess of acid, not bisulphate. Those questions were of great importance to those who were not superphosphate makers. There was one great advantage about the 5-ton still, that it lasted a long time. He had known a cast-iron nitric acid pot to last 20 years, and it would be interesting to know if the life of this still could be measured by any comparison with that. Mr. Prentice had committed himself to the statement that this still was 10 times as enduring as the 5-ton still which he formerly employed, so that if the 5-ton still would last 20 years this would last 200.

MR. MANNING PRENTICE said, so far the still in operation did not appear to have deteriorated at all, either the still itself or the top, so that experience was still lacking as to the relative life of one part of the still or another. With regard to the statement that this still would last 10 times as long as the other, he thought it was true, but he did not quite see how he was to demonstrate it. It was absolutely impossible to say how long one of these stills would last, but he said, advisedly, the place where former stills wore out was where the nitric acid condensed upon the cooler surface and trickled down. In his still there was no alternate heating and cooling, and therefore no condensed nitric acid trickling down. If the wear of the still were caused entirely by trickling nitric acid, and there were none, the still must last for ever. With regard to the percentage of acid used it was very uncertain what the percentage ordinarily used was, for, as far as he could gather, it differed much with different makers. With his still they generally used about 12 parts by weight of acid to 10 of nitrate of soda, but the question of the weight of acid would depend on a variety of considerations. In some works there was considerable advantage in having a large excess of acid. In some places a certain amount of weak nitric acid might be used mixed with the oil of vitriol.

MR. T. TYLER observed that a good deal depended on the strength of the acid used, whether it was chamber, brown, or concentrated acid. He had seen this apparatus working and was pleased with it, and therefore he hoped Mr. Prentice would give as much information as possible. If Mr. Prentice could say that 10 parts of practically dry nitrate of soda mixed with 12 parts of sulphuric acid of a definite strength, saying what that strength was, produced a fluid outflow of low acidity, and what the acidity of that outflow was, something definite for guidance would be gained.

MR. MANNING PRENTICE said by 12 parts of sulphuric acid he meant 12 parts of oil of vitriol. With regard to the acidity of the resulting eake he had not the figures before him. The fact was he had not written a paper on this subject, but this model had come to London for the purpose of being sent abroad, and it occurred to him that a sight of it might interest some members of the Society, and he had therefore brought it forward, but he was not prepared to give the exact figures as to nitric acid making. They were making, however, good nitric acid of full 1500° sp. gr., which was running in a continuous stream of a pale straw colour. For makers who wanted nitric acid of a lower gravity there

was no necessity to use oil of vitriol, a weaker acid could be used. There was no doubt that on a large scale nitric acid could be made very cheaply. He could imagine a constant stream of acid running from a Glover tower through this still, a constant stream of nitric acid running out from condensers, bi-sulphate flowing continuously from the exit, and superphosphate being wheeled away, so that the whole matter became wonderfully simple.

*Meeting held Monday, April 16th, 1894.*

MR. WM. THORP IN THE CHAIR.

#### MODIFICATION OF FERRIC CHLORIDE DISTILLATION PROCESS FOR ESTIMATION OF ARSENIC IN COPPER.

BY F. PLATTEN.

THE accurate estimation of arsenic in copper has become of late years a matter of great importance to manufacturers, on account of the influence exerted by this impurity on some of the mechanical and other properties of the metal.

With the great advance in electrical engineering has sprung up a demand for copper, with the maximum conducting power 100 per cent. is now stipulated for in the Post Office specification relating to wire, and as the presence of mere traces of arsenic is found to lower the conductivity to a serious extent (see *Electrolytic Separation of Metals*, G. Gore, p. 27), it is an absolute necessity to be able to detect and estimate extremely small quantities with certainty.

The question of how much arsenic may be present in copper without impairing its suitability for rolling purposes, does not appear to be yet settled, but, on the authority of an expert smelter, it may be stated that copper sheets have rolled well when containing arsenic to such an extent that the rolls were whitened by the fumes; unfortunately, however, no analysis is available.

In the manufacture of copper plates for locomotive fire-boxes, it has been the custom for some years for engineers to limit the arsenic to a maximum of 0.15 per cent., but this regulation was apparently ill-advised, for recent experience has shown that even up to 0.50 per cent. of arsenic has not proved in any way detrimental to the working properties of copper for this purpose; in fact, the reverse is now supposed to be the case, and the limit is accordingly being relaxed, but while it was in force the variation in the analyses of different chemists gave rise to endless trouble.

Various methods have been proposed for estimating small quantities of arsenic in copper, and of these the one in use at the Tharsis Works at Oldbury seems to be most generally adopted.

It consists of dissolving the metal in nitric acid, adding ammonia in excess, and saturating with sulphuretted hydrogen.

The ammonium sulphide formed, precipitates the copper as sulphide, while the arsenic is retained in solution.

The cupric sulphide is then filtered off, washed with dilute sulphide of ammonium, and to the filtrate containing the arsenic is added hydrochloric acid in excess; this decomposes the ammonium sulphide, and arsenic trisulphide, accompanied with much free sulphur, is thrown down.

The precipitate, after being filtered off, is oxidised with fuming nitric acid and the arsenic acid precipitated with magnesia mixture and weighed on a tared filter after drying at 95–100° C.

There is undoubtedly a tendency for cupric sulphide to retain arsenic even when precipitated in an ammoniacal solution, but with ferrous sulphide the case is different, and the following method takes advantage of this point, and is

said to be very accurate (see Crookes' Select Methods in Chemical Analysis, p. 439), but it requires special precautions and great care.

The metal is dissolved in nitric acid and a small quantity of ferric nitrate added, the solution is then nearly neutralised with sodic hydrate and excess of sodium acetate added.

The solution is then heated to boiling and filtered as rapidly as possible, the precipitated ferric acetate dissolved in hydrochloric acid, ammonia added in excess, and sulphuretted hydrogen passed to saturation, and from this point the process is identical with the one already described.

The great danger is the precipitation of a basic acetate of copper with the iron, when there is nothing for it but to throw out the solution and commence again.

It is said to be possible, after precipitating arsenic trisulphide and cupric sulphide in an acid solution, to render the mixture free from arsenic by digestion with yellow sodium sulphide, but even if it were so the method would be extremely laborious, as it would be indispensable to treat the precipitate four or five times.

A method suggested by Fresenius (see Quant. Analysis, p. 469) is to pass dry chlorine gas over the finely-divided metal, volatilising the chloride of arsenic; but it is not practised, principally, no doubt, on account of the objections to the use of chlorine in the laboratory.

Generally speaking, the amount of arsenic present in the commercial copper is small, and it is on this account that a fair quantity of the sample—not less than 10 grms.—must be taken for analysis, and the manipulation of this quantity in processes which involve precipitation and washing is a serious matter. A method which is fast superseding all others is known as the ferric chloride distillation process, which depends on the volatility of arsenious chloride.

A very convenient way of conducting it, is to take 20 grms. of ignited ferric oxide, dissolve in 150 cc. pure hydrochloric acid, and transfer to a Wurtz flask connected with a condenser, and distil over about 50 cc. of hydrochloric acid.

If this distillate gives no trace of arsenic on treatment with sulphuretted hydrogen, it may be taken that the reagents are free from arsenic, and the copper to be analysed may be introduced into the flask.

10 grms., preferably in the form of drillings, are taken and the distillation carried on till about 150 cc. of the liquid has distilled over; this will as a rule contain the whole of the arsenic, but it is best to change the receiver, add more hydrochloric acid, and test a further distillate with sulphuretted hydrogen.

The arsenic is then precipitated with sulphuretted hydrogen, the arsenic sulphide filtered off, washed, dried, and then treated with carbon disulphide, and finally weighed on a tared filter after drying at 100°.

This method was introduced by Dr. John Clark in a paper on the estimation of arsenic in pyrites (see Journal of the Society of Chemical Industry, May 1887), and the results then published were of a highly satisfactory character.

He recommends, in the case of large quantities of arsenic, direct titration of the distillate with iodine solution, but when inconsiderable, the precipitation with sulphuretted hydrogen as stated above.

The percentage of arsenic in commercial copper is rarely, if ever, high enough to admit of directly titrating the distillate, so that up to the present the usual course has been to weigh the arsenic sulphide.

This necessitates the use of tared filters, which is generally admitted to be unsatisfactory; certainly a margin of a milligram is the minimum that must be allowed, and this is frequently insufficient, and, when the prolonged washing of the precipitate and subsequent treatment with carbon bisulphide is taken into consideration, it will be seen that discrepancies are almost certain to occur.

In the present communication an account will be given of a modification touching on this point, whereby it is believed that a considerable saving in time must result to the many chemists who are using this deservedly popular method.

Now arsenious sulphide is commonly supposed to be unacted on by water, and it may be interesting to quote Fresenius on the subject, as follows:—

" . . . . . When boiled with water or left for several days in contact with that fluid, it ( $As_2S_3$ ) undergoes a very trifling decomposition—a trace of arsenious acid dissolves in the water and a minute proportion of sulphuretted hydrogen is disengaged; this, however, does not in the least interfere with the washing of the precipitate" (obtained in the course of a quantitative analysis).

It is presumed this refers to cold water, although the point is not quite clear—certainly it is unsafe to wash in hot water—for appreciable quantities of arsenious sulphide are frequently found to appear in the filtrate on standing, and it was the observation of this fact which suggested a careful inquiry into the extent of the action of water on the sulphide.

It is undoubtedly greater than is generally supposed, and instead of weighing the small quantities of arsenious sulphide obtained by the distillation process, it is found to be far preferable to boil the sulphide in water, and, when dissolved, titrate the solution of arsenious acid with centinormal iodine, and excellent results have been obtained in a great number of analyses. After transferring the sulphide to an ordinary flask, no further attention is required; it may be placed on an iron plate and left to boil, and any number can be dealt with at the same time.

It is usually found that solution is effected by boiling in 400 to 500 cc. of water in one to two hours, but it is best to boil, for a few minutes after the last trace of colour has gone, to thoroughly expel sulphuretted hydrogen.

It is interesting to note that commercial sulphide of arsenic is said to be always contaminated with arsenious acid (see Taylor on Poisons in Relation to Medical Jurisprudence and Medicine, 1875 edition, pp. 354—356), but the test by which this conclusion is arrived at is evidently misleading, which reads: " . . . . . the powdered sulphides yield a solution of arsenious acid on boiling with water acidulated with hydrochloric acid, and this sometimes amounts to as much as 30 per cent. . . . . " It will be seen at once that if only a small quantity of arsenious sulphide were taken in such an analysis, a much higher result might be easily obtained, inasmuch as the whole of the sulphide might be converted by boiling into the soluble arsenious acid. Apparently the only reference published is in a method devised by MM. Clermont and Frommel for the separation of arsenic, antimony, and tin when present as sulphides, which will be found in Comptes Rendus, No. 13, April 1878, and from which the following is extracted.

The mixture of sulphides is to be washed with the greatest care, as the minutest trace of hydrochloric acid would occasion a loss through the volatilisation of arsenious chloride; the mixture is then washed into a flask and boiled with pure water, a current of air materially aiding the solution.

Unless the quantity of arsenic exceeds one-fifth of a gm., the dissociation of the sulphide is complete after distilling 500 to 600 cc. water, and on filtering the whole of the arsenic is found in the filtrate as arsenious acid.

Before relying on this reaction and adopting it permanently, the following experiments were made in the metallurgical laboratory of the Mason College under the supervision of Mr. T. Turner.

Two separate analyses of a sample of copper sheet were made by the distillation process, and the arsenious sulphide carefully washed, treated with carbon bisulphide, and weighed, the results being—

	Per Cent.
I. . . . .	0.707
II. . . . .	0.719

average 0.713, a variation of 0.012 gm., or 1.6 per cent

To ascertain if the whole of the arsenic is expelled in this process, a solution of arsenious acid was carefully made up, and varying quantities added to the distilling flask, with the usual quantity of the purest electro-deposited copper,

from which it was impossible to get a weighable quantity of arsenious sulphide. The results were as follow:—

	Arsenic introduced.	Found.	Excess.
	Mgms.	Mgms.	Mgms.
1	9.048	9.75	0.7
2	22.62	25.42	2.8
3	46.79	47.98	1.19

which results are fairly satisfactory considering the small amounts dealt with and the liability to error in using tared filters. It may be noted that there is an excess in each case, which may be accounted for in a measure by the fact that the electro deposited copper contained arsenic, but not in weighable quantity. To test if there is any loss on boiling the sulphide the following experiments were carried out. A carefully prepared solution of arsenious acid in hydrochloric acid was made and various quantities treated with sulphuretted hydrogen, filtered, and the precipitate washed into a 30-ounce flask, filled up with pure water, boiled, and, when completely dissolved and colourless, titrated with centinormal iodine standardised with the arsenious acid solution. The following are the results:—

Arsenic introduced.	Found.	
Mgms.	Mgms.	Mgms.
3.74	3.78	0.04 excess.
7.48	7.36	0.12 loss.
18.81	18.57	0.23 "

which will no doubt be considered conclusive. Finally, the arsenical copper, which gave 0.713 per cent. arsenic by distillation and weighing the sulphide, was again determined by solution and titration of the sulphide, the figures in two separate analyses being—

$$\left. \begin{array}{l} 0.683 \\ 0.675 \end{array} \right\} \text{average } 0.679 = 0.034 \text{ per cent. less.}$$

It is seen that the result by iodine method in this case is somewhat lower, but this hardly detracts from the value of the experiment, for it is invariably found with impure coppers, with which this sample must be classed, that there is a dark insoluble residue left on boiling the sulphuretted hydrogen precipitate.

These residues have been tested in several cases and have been found to contain antimony, so that when the arsenious sulphide is weighed this antimony precipitate would be included and appreciate the result.

In conclusion, it is not considered that sufficient data have been given to claim for this modification any superiority except in point of saving time. It will readily be seen, however, that if the weighing of filters (in itself a most laborious task), careful washing with carbon bisulphide, and finally weighing several times, can be dispensed with in favour of boiling the precipitate and titrating, hours of labour may be saved, and the saving will be in direct proportion to the number of estimations on hand.

It should be mentioned that the freshly precipitated sulphide is more easily dissolved than if left to stand, and that it is quite unnecessary to wash the precipitate free from hydrochloric acid.

MM. Clermont and Frommel state that the minutest trace of this acid will cause a loss, but this is certainly not the case. In addition to the foregoing experiments, in which no washing was done, a special test was made to determine this point by boiling a precipitate transferred from the filter-paper without washing at all for several hours in a Wurtz flask connected with a condenser. The distillate gave no trace of arsenious, and it may be safely assumed that even were arsenious chloride formed it would be instantly decomposed by the excess of water present.

## DISCUSSION.

The CHAIRMAN said Mr. Platten seemed to have hit on one of those apparently simple things which made a great difference in the amount of labour involved. The chemistry of his modification would be patent to all.

Mr. SUTHERLAND said he had to use the process of distillation by means of ferric chloride very frequently in estimating the arsenic in commercial copper, and he had found the process extremely reliable. He had not found any great delay involved in the case of the chloride being titrated direct with iodine; he always found the results very satisfactory. The sulphide could be treated with nitric acid and titrated with uranium acetate, the results being likewise accurate. A very suitable method for estimating arsenic gravimetrically had been suggested to him some years ago by Mr. Blount, viz., dissolving the sulphide in ammonia, evaporating down, and then weighing. He had himself used this method frequently, and found the results came out very accurately. He should like to ask Mr. Platten if he had compared the results of these processes with those he had obtained in the one he had now described.

Mr. PLATTEN said the only objection he could see to the ammonia process was that ammonia dissolved appreciable traces of sulphur; and very frequently sulphide of arsenic, from some cause or other (as a rule impurities in the ferric chloride or perhaps in the acid), when precipitated, was contaminated with sulphur, which would be dissolved in the ammonia, and so increase the result.

## THE TREATMENT OF GOLD ORE AT THE WITWATERSRANDT (TRANSVAAL) GOLD-FIELDS.

BY HENRY DE MOSENTHAL, F.I.C., F.C.S.

I HAVE lately returned from the Transvaal, where I spent some months. Whilst there I visited a number of mines, and, thanks to some of the leading mining engineers and chemists, who gave me, in the kindest manner possible, the information I sought for, I was able to investigate the methods employed for the winning and recovery of gold in the Witwatersrandt district.

As I have been unable to find any recorded general account of the methods employed, and the difficulties to be overcome, I have ventured to think that a description of my experiences and observations may not be without interest to the members of the Society.

I wish to record here my thanks to Mr. Hennen Jennings, one of the leading mining experts, who showed me some of the plant recently erected under his superintendence; to Mr. William Bertel, the senior chemist at the well-known Robinson mine, who gave me the benefit of his experience, and devoted considerable time to preparing notes for my guidance and samples for my collection; and to Mr. Charles Butters, who kindly allowed me to visit the works of the Central Ore Reduction Company.

I do not presume to discuss the merits of the various methods employed; my object is rather to give an account of what I saw, and record the information I have been able to gather.

Johannesburg, the great centre of the gold-mining industry, is a town of some 30,000 white inhabitants, and on seeing it no one would believe that it is but six years old. There are mines on the very outskirts of the town, and on both sides they extend, mostly in single file, along the main reef. Their appearance is very similar. A head-gear and hauling machinery, situate sometimes at a distance from, sometimes in close proximity to the mill; cyanide works, erected, or in course of erection, near the mill; dams or reservoirs in which the rain-water, and the

water pumped out of the mine, is collected; and settling-dams for the tailings and slimes, are what you see everywhere.

The general impression is certainly most striking. About 80 mines (including the deep levels), one next to the other, the majority having extensive machinery and plant, most of which has been brought there by ox-waggon before the railway line was made. A gigantic industry sprang up in a wilderness nearly 1,000 miles from the principal seaport. The difficulties that had to be overcome were numberless.

The railway has now created greater facilities, but still labour is very dear, and the price of all commodities remains excessive. According to recent statistics published by the Johannesburg Chamber of Mines, 3,200 white and 21,000 coloured workmen were employed at the mines at wages averaging 16s. to 18s. a day for the former, and 2s. to 3s. a day for the latter.

These remarkable goldfields are situated on a high plateau at one of the highest points of South Africa, which entire country rises terrace-like from the sea. The gold-bearing district has the shape of a shallow basin bordered to the north by a sandstone ridge, which forms the watershed between the Orange River, which flows into the Atlantic and the Limpopo River, which flows into the Indian Ocean; and to the south by hills of Trap Rock. A large number of reef-groups have been found in that area, the chief group being the so-called main reef series, which includes the north reef, main reef, main reef leader, middle reef, and the south reef; which, together, cover an extent of nearly 40 miles from east to west; the other groups of reefs being found chiefly to the south, and parallel to it.

Johannesburg is situated close to the main reef, 4,772 feet above the level of the sea, whilst other points on the main reef attain an elevation of 5,500 feet. The whole area occupied by the mines of the Witwatersrandt district is about the size of London, including the suburban districts.

Within this area coal has been discovered, and in a country like the Transvaal, where wood is scarce, this discovery of coal has alone made it possible to develop the gold industry in so marvellous a manner.

The coal has about 60 per cent. of the caloric value of English coal, and was selling in December last at 22s. per ton, delivered at the gold mines. The price would be lower were it not that the railway company will not carry coal in bulk. A sack, which contains 2 cwt., lasts only three journeys, and costs 9d. at Johannesburg; so that the compulsory use of sacks increases the cost of coal by 2s. 6d. per ton.

This local coal, in consequence of the large percentage of ash, makes very inferior coke, so that it cannot be used for assaying or refining. For these purposes English coke must be used, which was selling at 14l. per ton.

As to the occurrence of gold, some believe that this flat basin was once a lake, and that the gold was deposited there. Of course this is in dispute, and numberless other theories have been started.

I may mention here that a large section of the Boers—and I understand that Mr. Christian Joubert, the Minister of Mines, is of the number—firmly believe that there was no gold in the ground as long as the country was under British rule, but that after the successful war of independence God placed the gold into the earth to reward His faithful people.

The formation is so different from that in which gold is known to occur in other parts of the world that geologists and mining experts would not believe at first that the gold would hold out to any depth. It does not occur in quartz, but in a conglomerate or pudding stone, which is locally termed "banket," this being the Dutch name for the sweet-meat we call "almond rock." The banket consists of pebbles held together by a silicious cement, which contains crystals of iron pyrites. Above the permanent water-line the pyrites in the banket cement has become oxidised through the action of air and water.

Thus the rock is more oxidised at the surface and less so as you descend; the greater the depth the more pyritic the rock.

The oxidised rock, which in mining language is termed "free milling" ore, as against pyritic or "refractory" ore, is very friable.

The gold, which is so fine as to be but rarely visible even with considerable magnification, occurs almost exclusively in the cement which holds the pebbles together; sometimes it has been found in the pebbles themselves, but then only in cracks in the quartz.

In the pyritic ore the gold is finely distributed among the iron pyrites.

I possess a number of thin sections prepared for the microscope, both of the oxidised and the pyritic rock, two of which are represented in the annexed microphotographs. The quartz pebbles polarise in the well-known manner, whilst the cement which holds them together, being amorphous, does not. In the pyritic ore the crystals of iron pyrites can be seen embedded in the cement. The cement consists chiefly of finely-divided particles of amorphous silica. An analysis of the oxidised cement showed it to consist of:—

Silica .....	87.4
Oxide of iron .....	10.8
Water .....	1.8
Lime .....	Traces.
Magnesia .....	"
Alumina .....	"
	100.0

I have some particles of gold extracted from rich pyritic ore by means of nitric acid, and I have examined this gold microscopically. I find that it consists of very fine laminae or specks. When viewed with transmitted light some of these laminae show the well-known green colour of translucent gold leaf, only darker, due possibly to the presence of silver, which may also account for some appearing bluish; some, again, are of a bright red, which has been observed to be frequently the colour of finely-divided gold; the tints vary considerably. Viewed with reflected light they nearly all appear yellow, orange, or red, and have a metallic lustre. Some of the specks show crystalline structure, but in most I have been unable to detect any trace of crystallisation.

Some of the gold is associated with sulphides of the base metals, and these auriferous sulphides are spoken of as sulphurets.

The fine distribution of the gold and the presence of sulphurets are generally held to account for the difficulties which have been encountered in the extraction, and I shall have to refer to this as we review the various processes.

The reef, which consists of banket, as I have said, is bordered by a kind of sandstone, the hanging wall and foot-wall being the same all through the main reef. Some of the other reefs have a more shaly foot-wall, and in some mines the foot-wall and hanging wall, are quartzose sandstone.

None of the mines at present worked are deep, most of the workings being about 300 or 400 feet below the surface. In the so-called deep level mines recently tested—with the exception of the Randt Victoria Deep Level, which has a borehole 2,400 feet deep—the reef has been struck at less than 1,500 feet.

The reef in some of the mines which have been worked hitherto descending at an angle of about 45°, it was thought that deep borings further on would strike the reef again. This assumption proving correct a large number of deep-level workings are now being opened up. The reports of competent mining experts go to show that in these deep levels the reef continues of the same nature as above, and bears about the same average quantity of gold. Shafts have been sunk in several of these deep-level mines and large batteries are to be erected to treat the ore.

I shall not enter into a description of the underground working, my object being to describe what is done with the ore after it has been obtained and drawn up out of the mine by strong hauling-gear to the top of the head gear.

If the stonebreaker is in the mill the ore is at once taken there, but in most cases the stone-breaker is placed in the head-gear, and this is naturally more economical in a flat country.

The same section of oxidised basket — 50 photographed with reflected light.

Section of pyritic banket - 50 photographed with transmittant light.

The same section of pyritic banket - 50 photographed with reflected light.

In most of the mines which have been more recently started, or which have been supplied with new plant, the head-gear contains a Gates or comet crusher, and a sorting floor as here shown.

When the ore reaches the top of the head-gear the skip in which it is contained is tilted—in the more recent plants this is done automatically—and the ore falls on to the sorting floor.

On this sorting floor the ore is sprinkled with water, which renders it easier to distinguish the country rock from the auriferous banket, and the former is as far as possible thrown out by hand, the latter being thrown into the crusher.

The Gates or comet crusher, now greatly in favour on the Randt, consists of a spindle which oscillates eccentrically.

A description and drawing of this crusher will be found in Eissler's "Metallurgy of Gold."

Most of the machinery in the mills and head-gear at the Transvaal mines have been supplied by the Sandycroft Foundry Company, and by the well-known firm of Fraser and Chalmers.

The diagram at the bottom of previous page shows a plan of a mill with Grizzly B, and the rock-breaker C within the building. It is to this drawing that the capital letters in the text refer.

In the mines which have not got the new plant above described the well-known Blake stone-breaker is used together with the Grizzly, which consists of iron bars placed 2 inches apart, so that the small pieces fall straight into the ore bin and not into the crusher. This Grizzly and Blake crusher are more frequently to be found in the head-gears than in the mill itself, as above mentioned.

From the ore bins in the head-gear the crushed ore is brought to the ore bins in the mill, and passes into the automatic feeders E, and thence gradually into the mortar F. The mortar is that portion of the mill which contains the stamps. Five stamps act in one mortar.

A mortar of the more recent kind with internal amalgamation plates is here shown:—

Fig. 2.

a Stem (wrought iron). b Head (cast steel). c Shoe (forced steel).  
d Die (forged steel). e Steel liner. f Mortar (cast iron).  
g Copper plate for internal amalgamation. h Ore feed. i Screen.  
Drop of stamp at j = 9 inches.

Some mortars have the inside amalgamation plates placed somewhat higher up than shown in the drawing, because they are then less liable to be damaged by the strain of the falling stamp.

The ore is kept wet by a constant supply of water. The copper plates *g g* are covered with mercury in the same way as the external plates or aprons G, of which we shall have to speak presently. Mercury is dropped into the mortar. The quantity of mercury thus dropped in is regulated according to the appearance of the mercury on the apron, which must never become too fluid.

This mercury combines (amalgamates) with some of the gold, and some of the gold is caught on the internal amalgamating plates. The crushed ore or pulp and some of this internally-formed amalgam, as well as the excess mercury, is discharged through the screen which is fixed in the front portion of the mortar. The stamps weigh from 900 to 1,200 lb., each the heavier ones being the more recent. They are raised by cams and allowed to drop. In most of the mills the stamps drop on an average 92 times in a minute. The latest style of stamp crushes  $4\frac{1}{2}$  to 5 tons in the 24 hours when a 900-mesh screen is used (900 holes to the square inch or 30 to the linear inch). Some mills use coarser, others somewhat finer screens, but in most cases 900-mesh screens are used. In December 1893 the average for 52 mills with a total of 2,175 stamps was 3.65 tons per stamp head per diem. The quantity discharged is fairly even and the pulp flows in a thin film over the amalgam plates G which form the apron, and here a considerable portion of the gold is caught. As the dies wear a chuck-block of a less height is put underneath the screen in order to regulate the discharge.

The photographic view on next page shows the new battery of the Robinson Company. The screen has been removed from the mortar to the right, so that the heads of the stamps with the shoes and dies can be seen.

The amalgam plates are made of very porous copper, which is thoroughly cleaned and then coated with mercury, which forms on the lower surface an amalgam with the copper. The mercury must not form drops, and the upper surface must be kept bright. Some use a little potassium cyanide solution for preparing the plate before the mercury is put on it. The gold being heavy falls on to the mercury, as also does the amalgam which has been formed in the mortar and is there retained. It has been the experience of amalgamators that the coarser and purer the gold the more remains on the plates. It has also been found that the chief amalgamation takes place on the plates within the mortar, and on the first 3 feet of the aprons, which are usually 6 feet wide by 12 feet long. The surface of the mercury has to be kept clean, as above observed, otherwise the gold will not amalgamate. The incline given to the plate, which determines, of course, the velocity of the flow of water, is also a question which is ascertained by experience. If the plate is not sufficiently inclined a great deal of sand and other impurities collect thereon, whilst if it is too much inclined the water carries away too much gold. In some mills, as many as three plates are placed the one after the other in cascade fashion, as it was thought that the drop from the one to the other rendered it possible to collect more gold, but single plates have found more favour, and some of the mills that formerly had three plates have now only one. With very fine gold the quantity carried away by the water is naturally greater. In fact we shall see that the degree to which the gold in finely-divided particles will remain in suspension in water is most remarkable.

This "float gold," as it is termed, and the sulphurets, do not amalgamate on the plates, neither does the gold which is held between the particles of iron pyrites.

I am informed that in most of the mines in the United States, Venezuela, and Australia, the gold is comparatively coarse and pure, and about 75 per cent., in some cases even 80 per cent., thereof is caught on the plates. At the Witwatersrandt, however, only about 55 per cent. to 60 per cent., and frequently less, remains on the plates. I have also been told of some few mines in other parts of the world where the yield on the plates was less still, but 60 per cent. is generally considered a very low percentage, especially for ores averaging under one ounce to the ton.

I understand that in some mines in other countries the plates are continually cleaned by means of india-rubber

stamps without stopping the mill. On the Witwatersrand the stamps have to be stopped for cleaning the mercury, which is done twice a day.

A clever amalgamator, who understands how to prepare and attend to the plates, and how to subsequently treat the amalgam properly, is a man much sought after.

The quantity of mercury lost depends to some extent on the care bestowed on the treatment, but chiefly on the nature of the ore. With heavily sulphuretted ores the loss is much higher than with ordinary quartz.

Thus, with pyritic blanket, in spite of all care, the loss of mercury is high, it being about three-quarters of an ounce to the ton of ore treated, whilst I understand that in California the loss of quicksilver is reckoned at 1 lb. to 32 tons of ore crushed, or half an ounce per ton.

A small part of the loss is usually accounted for by carelessness, and there is always some loss in the hereinafter described cleaning and retorting of the amalgam; but the larger portion of the loss is usually attributed to the so-called "flouring" of the mercury on the plates, which causes some of it to be carried away by the flowing water.

As most of the mines on the Randt are milling highly pyritic blanket, the loss on an average seems to be very close to an ounce a ton. The total amount of ore crushed in 1893 was, in round figures, 2,200,000 tons, which represent approximately a loss of 140,000 lb. of mercury. The mercury is sold in iron bottles containing from 72 lb. to 75 lb., and these bottles are sent out to South Africa. The present price is 5*l.* 10*s.* per bottle, so that the annual consumption of mercury on the Randt can now be put down at about

THE NEW BATTERY AT THE ROBINSON MINE.

2,000 bottles of a value of 11,000*l.*, without taking into account the mercury required for starting new mills.

The gold amalgam which has formed on the plates is collected and cleaned in a specially designed clean-up pan, or else ground in iron hand pans with iron balls, and sometimes in revolving barrels.

The degree to which this grinding operation is carried out is a matter which requires experience.

When sufficiently ground, the amalgam is flooded, that is to say, it is thrown into a quantity of mercury, in which it partly dissolves and partly falls to the bottom, whilst the impurities remain on the top and are skimmed off.

These impurities are collected and mixed with the concentrates, of which we shall have to speak presently.

I have examined some of these impurities and find that they consist mostly of particles of pyrites and particles of silicious matter, both crystalline and amorphous.

The cleansed amalgam, with the excess of mercury, is placed in a press, the lower portion of which consists of a perforated plate, covered with filtering cloth, made of twill, such as is commonly used in filter-presses, and the excess of mercury is pressed off. The dry hard amalgam,

which has a silvery appearance, is then placed in a retort, which ends in a tube surrounded by water.

Heat is applied gradually to the retort, and this causes the mercury to volatilise. The mercury vapour passes through the tube, and is condensed and recovered, whilst the gold remains behind in the retort. This gold is then melted in a large plumbago crucible with a small quantity of flux, and the impurities are skimmed off. The pot, with its contents, is then lifted up, and the gold is poured into cast-iron moulds to form ingots of 1,000 ounces each.

This gold varies from 800 to 850 per mille in fineness. It contains some silver and a proportion of base metals.

The "pulp," as it runs off the copper plates, is conducted in most mills through wooden gutters or sluices, then on to concentrators. In some cases blankets are used, and some mills have Slinger tables, but in most cases Frue vanners, & J., are used, and this latter class of concentrator is becoming more and more general on the Rand.

In all these mechanical devices the principle is the same, viz., to separate by gravity the heavier particles from the lighter.

The Frue vanner consists of an endless inclined rubber belt of 4 feet wide by 12 feet long, supported by rollers and bordered on the sides by rubber flanges. The belt travels up the incline and around a lower drum, which dips into a water tank where the mineral is collected. In addition to the travel of the belt, the latter receives a steady shaking or settling motion from a crank shaft along one side, the shake being at right angles to the inclination and travel of the belt. Over this belt there is a distributor, the lower part of which is formed by a copper plate which is coated with mercury. The pulp enters from above through a 3-foot aperture in the distributor, and some of the free gold which has escaped amalgamation is here caught by amalgamation with mercury. This amalgam is collected and added to that taken from the inside plates and the apron of the batteries.

The rapid shaking motion of the vanner keeps the lighter portion of the pulp in suspension in the flowing water, the heavier portion, consisting largely of auriferous iron pyrites, adheres to the india-rubber, and is brought forward and washed off as the belt passes round into the water tank below, where the concentrates are collected. Water emanating from a row of small spouts washes back the lighter sands and particles which flow over the belt in the direction of the incline, therefore in the opposite direction to that taken by the concentrates, and they are conveyed through wooden sluices into the settling-dams. This pulp which flows off still represents the almost entire bulk of the ore crushed. The concentrates collected amount on an average to somewhat less than 3 per cent. of the total weight of ore crushed, and I understand that in other parts of the world where pyritic ore is treated the percentage of concentrates collected is about the same.

There is a considerable amount of discussion as to the importance of having the best mode of concentration. Most of the experts on the Randt consider careful concentration of the greatest importance, and the Chamber of Mines of Johannesburg decided to offer a prize—I believe it was

3,000*l.*—for the best concentrator. Some, again, consider concentration superfluous, and in some mines it is dispensed with, the pulp being treated differently, as I shall mention further on.

Most mines concentrate, and the Frue vanner system is the one at present most in favour.

The concentrates are very rich in gold, containing from 5 to 8 oz. to the ton. They are roasted and treated by chlorination.

Most of the mines sell their concentrates to one of the two chlorination works at the Randt, viz., the Robinson Company or the Randt Central Ore Reduction Company. Mr. Charles Butters designed both these works, started the former, and is now managing the latter, so that the methods employed are practically the same in both.

The mines sell their concentrates at 90 per cent. of the assay value, less 4*l.* per ton for treatment.

In treating concentrates by chlorination 95 per cent. of the gold is extracted, and in addition to this difference between 90 per cent. of the assay and the actual extraction there is a profit on the 4*l.* for treatment. What the chlorination treatment actually costs in the Transvaal it is difficult to say, as a good deal must depend upon the manner in which the general expenses are calculated, but I have heard the figure of 3*l.* mentioned as the average cost. Of course it would not be possible to treat any but rich material by this method, which requires nearly an ounce of gold per ton to cover the cost.

The concentrates are placed in reverberatory furnaces, with abundant admission of air. The consumption of fuel to effect the roasting is 60 per cent. of the weight of the concentrates.

It must be borne in mind that, as stated already, this would mean about 35 per cent. were English coal used, as the Transvaal coal makes so much more ash.

The percentage of iron pyrites ( $\text{FeS}_2$ ) in the concentrates varies considerably, but is seldom more than 35 per cent. or 40 per cent., so that the concentrate

rarely contain more than 20 per cent. to 25 per cent. of sulphur. I have, however, known of samples to run as high as 40 per cent. of sulphur.

The purpose of thus roasting the concentrates is to drive off the sulphur and any arsenic which may be present, to oxidise the iron pyrites to ferric oxide (red oxide of iron  $\text{Fe}_2\text{O}_3$ ), to disintegrate the dense cubic crystals of the pyrites, and to oxidise the other base metals.

At the Robinson mine common salt is, towards the close of the operation, thrown into the furnace to assist the oxidation and produce a preliminary chlorination. I understand that at the Randt Central Ore Reduction Company's Works this is dispensed with. Whether salt be used or not depends upon the temperature of the "roast" and the air supply.

In addition to the reverberatory furnaces, finishing hearths are used, as it is of the greatest importance to roast the ore dead, the smallest percentage of sulphur affecting the

extraction considerably;  $\frac{1}{2}$  per cent. of free sulphur would make a difference of 15 to 20 per cent. in the yield. I am told that a bad roast can never be cured.

During the roasting dust accumulates in the flue boxes, and as this contains gold, sometimes in considerable quantities, the flues are periodically cleaned and the flue dust mixed into the next charge of concentrates.

The roasted concentrates are moistened. They ought only to contain 6 per cent. of moisture, but as a rule the moisture varies, according to the condition of the atmosphere, between 8 and 12 per cent.

Chlorine gas has no effect on the dry material; any excess above 6 per cent. of moisture is found to cause a waste of chlorine.

The roasted and moistened concentrates are placed in large wooden vats, termed chlorination vats, the bottom of which is fitted with a filter made of brick, pebbles, and sand.

These vats are closed with a lid rendered gas-tight by a water lute. Chlorine gas is introduced from below and allowed to act from 18 to 36 hours.

The chlorine used is produced at the works in lead-lined steam jacketed generators, in which dilute sulphuric acid, salt, and manganese dioxide are mixed; the chlorine thus produced contains about 6 per cent. of  $\text{HCl}$ .

When it is judged that the gas has been in contact with the ore long enough to convert all the gold into the chloride—18 to 36 hours—water, preferably warm, is introduced, and the chlorine gas is allowed to pass into another vessel. The auric chloride, being soluble in water, enters into solution and is washed, or, to use the technical term, "leached" out.

The solution is run into tanks (marked on the drawing as "precipitating tanks"). This solution contains, of course, the chloride of gold and small quantities of chloride of silver; this latter salt being but slightly soluble in water in the presence of other chlorides, most of it remains in the residue. In addition to this, we find in the solution copper, cobalt, alumina, lead, traces of iron, traces of arsenic, traces of lime, and, when salt is used, sulphate of soda.

The ore having been washed or leached several times is dug out and thrown away. These residues contain only 2 or 3 dwts. of gold to the ton.

The chlorination liquor contains, besides the above impurities, a good deal of excess chlorine and a considerable quantity of oxide of iron and silica, which escape through the filter into the solution.

Sulphuric acid is added to keep the basic salts in solution, and then ferrous sulphate ( $\text{FeSO}_4$ ) is added.

This ferrous sulphate is made at the works. At the Robinson mine it is made in a most peculiar but evidently very practical manner. The sulphuric acid has, until

recently, been obtained from Europe in iron drums, which are perfectly valueless. Water is poured into a vat, then sulphuric acid is added, and the iron drums are thrown in and allowed to dissolve.

The ferrous sulphate thus obtained is, together with the excess of dilute sulphuric acid, run into the chlorination liquor.

I may here mention that for some time past sulphuric acid works have been erected in the Transvaal about 15 miles from Johannesburg, but the consumption is comparatively small, amounting to 500 tons per annum at the utmost, and hence a high price has to be charged, especially as the cost of labour and of all imported articles is very high. (Nitrate of soda, 24*l.* per ton.)

The cost of imported sulphuric acid was about 25*l.* per ton laid down at Johannesburg. Now there is a heavy duty on it so as to protect the Transvaal Sulphuric Acid Factory, which sells chamber acid at 20*l.* per ton. (They have no concentration plant.)

The action of the ferrous sulphate upon the dichloride of gold is explained by the equation—

The gold precipitated by the ferrous sulphate appears of a purplish colour, and when examined under the microscope it is found to be in cubic crystals. This gold is collected, calcined, and melted with borax and carbonate of soda. The gold falls to the bottom of the crucible and is, when cold, broken away from the slag and collected. When sufficient has been obtained it is melted over again and formed into ingots. This chlorination gold varies from 870 to 980 per mille in fineness. It contains a good deal of lead, some iron, and a little copper, with traces of arsenic, as, in spite of the addition of sulphuric acid, some of the arsenic

is precipitated with the gold. Although as fine as 980 1000, this chlorination gold is at times very brittle and very difficult to retine. Mr. Denker, the senior chemist at the Mint in Pretoria, mentioned some very curious points regarding the obstinacy of some of this gold, which remained brittle after the most careful retining.

The liquor from which the gold has been precipitated still contains some gold in suspension and in solution (1 to 2 dwt. per ton of liquor). This is due to the dissolving action of the ferric chloride ( $\text{FeCl}_3$ ) counterbalancing the precipitating action of the ferrous sulphate. To obtain the gold left in the liquor it is run into another tank and allowed to stand over scrap iron, which reduces the ferric chloride into ferrous chloride. The liquor, which was acid through the presence of some of the hydrochloric acid contained in the chlorine and the sulphuric acid, then becomes neutral through the action of the iron, and the gold, together with traces of copper and lead, as well as basic arseniate of iron, are precipitated. The residue is collected, and contains a considerable amount of gold, sometimes as much as 200 oz. of gold to the ton dry weight. Of course the quantity collected is very small.

At the Robinson works, in which about 10,000 tons of concentrates are treated annually, they collect about six tons of this residue in the year. The residue thus collected is mixed with the concentrates in the furnace and roasted with them, as is the case with the impurities collected from the amalgam, as already described.

In this chlorination process the quantity of ferrous sulphate used is greatly in excess of that which is required to bring about the reaction, chiefly because the excess of chlorine and the impurities in the liquor are very considerable. Several means of remedying this have been suggested, but, as yet, none have been adopted.

We will now return to the lighter portion of the "pulp," which we last saw floating off the concentrators into the settling dams. These are large reservoirs constructed like water reservoirs. In the first dam the heavier particles settle. These are called "tailings," and consist of very fine sand. The water flowing off these tailings carries with it the still lighter particles, which settle in the next dam. This very light material is termed "slimes," or more correctly "battery slimes." When dry these slimes present the appearance of impalpably fine dust in caked lumps. They are soapy to the touch, and are chiefly composed of the silica which holds the pebbles together. The tailings have a sand-like appearance.

The tailings amount as a rule to 60 per cent. of the weight of the original ore crushed, and contain from 5 to 7 dwt. of gold to the ton. It was, of course, indispensable to have a cheap process to make it possible to treat these large quantities of comparatively poor material; the MacArthur Forrester cyanide process has supplied the want, and it is by this that the tailings are treated. The slimes, which amount to about 40 per cent. of the weight of the total ore crushed, contain 1 to 5 dwt. of gold to the ton, and have not been treated up to the present, for reasons which I shall be better able to explain further on. They constitute absolute loss.

The majority of the mines have cyanide plant, or are erecting the same; cyanide plant in course of erection was, as I have already observed, a leading feature in the district when I was there.

The cyanide process consists roughly in bringing the ore into contact with a solution of cyanide of potassium, to get the gold into solution, and then precipitate it out of this solution by means of zinc shavings.

Mr. MacArthur, in a paper which he read before this Society (this Journal, 1890, 267—270), gave an account of the MacArthur Forrester process.

It was, I believe, at the Randt that this process was first introduced on a large scale. It was soon found nearly impossible to agitate large masses of material in the vats, as at first suggested, and percolation had to be resorted to.

Circulating pumps were introduced, and the liquor allowed to percolate several times through the ore, whereby the surface contact was greatly increased.

Messrs. Butters and Clennel published in the "Engineering and Mining Journal" for 1892 two papers entitled "The

Chemistry of the Cyanide Process" and "The Cyanide Process in South Africa," which were reprinted in the Journal of this Society (November 1892), and from these it can be gathered how the process was applied at the time, and the opinions which prevailed as to the chemistry. The equation there given for the reaction is:

The authors further express the opinion that no doubt the oxygen converts a portion of the cyanide into cyanate, which, being unstable, is converted into the carbonate of potash, carbonic acid, and free nitrogen.

Messrs. MacArthur and Forrester recommend 75 per cent. cyanide, but a good deal of 90 per cent. was being used, and some mines were using 98 per cent.

The zinc replaces the gold in the auric potassic cyanide, according to the following equation:—

Metallic zinc alone precipitates gold very slowly if in dilute solution, but once gold is deposited even in traces on the zinc, this is converted into a galvanic couple—gold-zinc—and the galvanic action actuates the reaction with evolution of hydrogen.

What takes place can no doubt be expressed by the following equation:—

and this hydrolysis accounts for the fact that the quantity of zinc used is more than 100 times as much as is theoretically necessary in accordance with the first formula above given. The use of caustic soda, to which I shall refer hereafter, still further increases the consumption of zinc, because of the reaction—

The subsequent chemical reactions are excessively complicated, and of course the impurities contained in the solution play a considerable part.

It has been found that pure zinc will not precipitate the gold as readily as commercial zinc will, in consequence of the presence in the latter of a considerable percentage of lead, the presence of this third metal evidently increasing the galvanic action.

The very finely divided state of the gold in the Witwatersrandt gold ore, which is such a disadvantage in amalgamation, and which is the cause of the slimes running so high, is a considerable advantage as far as the cyanide process is concerned, because of course the infinite number of microscopic specks increases the amount of surface contact, and these minute particles are more readily dissolved than coarser gold would be.

The zinc is prepared in shavings, in order to increase the surface contact as much as possible. One pound of zinc, when cut up in the manner in which it is done at these mines, represents, I was told, an area of five square yards, or 2·31 acres to the ton. These zinc shavings can be closely packed, and then form a somewhat elastic bulk which is almost felt-like, and it is with this that boxes are filled, the zinc resting on sieves to enable the solution to rise up evenly through it, and also to afford means of easily removing the zinc from the deposited gold. There are several such boxes divided into compartments; those into which the strong solutions are led are termed "strong boxes"; the "weak boxes" being those in which the weak solutions are treated.

Although the arrangement may vary in detail, it is very much the same at all the mines.

The cyanide works consist of large tanks, as shown in the following drawing:—

These tanks, in most of the works, hold from 70 to 100 tons of tailings, and in addition one-third as much solution; so that one of these tanks will hold, say, 75 tons of tailings, and 25 tons of solution. At some works the vats are very much larger. At the Langlaagte Estate Mine, the tanks hold 400 tons of tailings, and the mechanical arrangements are somewhat different to those herein described.

The tanks are lined with a filter consisting of wooden framework, on which canvas sacking and cocoanut matting are placed in superposed layers. This arrangement varies a little in the different works. Below this filter there are

the eduction pipes, and at the very bottom of the tank there is a large central discharge closed by a door conveniently clamped.

The reason for this latter arrangement is that the tailings after treatment cannot be dug out, as are the chlorination

residues, on account of the poisonous cyanide which still remains in them, and they have therefore to be taken out through this door, and dropped into trucks running on a tramway, which passes between the stone-work which supports the tanks.

At some of the mines the tanks are, by means of a circulating pump, connected with sumps or reservoirs: in some the circular pumps have been dispensed with.

At the mines at which circular pumps are used the solutions are pumped on to the tailings, and allowed to percolate and run into the sumps, care being constantly taken to test the strength of the liquor. As a rule a weak solution is first passed through the tailings and allowed to run on to the weak zinc boxes, then a strong solution is pumped on to the tailings and run into a sump, then another strong solution is pumped on, so that ultimately the strong solution and the weak solution has been allowed to remain in contact with the tailings three times for 12 to 18 hours each time, and then the solutions are run into the zinc boxes. After all the solutions have been run through, the tailings are thoroughly washed with plain water, which is also allowed to run over the weak zinc boxes, or run into the sumps to be used in making up liquor for a subsequent charge.

At the mines at which no circulating pumps are used a succession of strong and weak solutions is used, the same as above mentioned, and they are also left in contact for 12 to 18 hours, but there the solutions are at once run into the zinc boxes. It is held by some that it is not safe to pass the liquor more than once through the ore, as they believe it causes a loss of gold.

The strength of solution varies somewhat at the various works, but the general tendency is to reduce their strength, as it has been found that weak solutions give better results.

The strongest solution I have seen used is 0.6 per cent., in which case the weak solution used was 0.3 per cent. In other works 0.4 per cent. and then 0.2 per cent. were used, and I have even met with 0.3 per cent. as strong and 0.1 per cent. as weak solution.

The amount of cyanide required to dissolve 190 ounces troy of gold is theoretically 1.53 lb., but in practice it is found that it takes at the very least 300 lb. to extract 100 ozs. of gold out of 400 tons of tailings.

This would mean  $\frac{3}{4}$  lb. of cyanide per ton of tailings treated, but none of the mines are working as low as this. Besides, it has been found that the more pyritic the ore the more cyanide is necessary. I found that at some of the mines they were using 2 lb. of 90 per cent. cyanide per ton of tailings, whilst at others the quantity was considerably less. At the Robinson mine, as will be seen from the statement given further on, the average in 1893 was 1.16 lb. per ton of tailings treated. In other mines, again, I understand that the quantity sometimes exceeds 2 lb. The average is no doubt below that figure.

To arrive at an approximate idea of the quantity of cyanide used on the Randt, I believe that 2 lb. per ton can be taken. This would mean for the 1,200,000 tons of tailings treated in 1893 about 1,200 tons for last year.

The consumption has been steadily increasing as one mine after the other erected cyanide plant. On the 31st December last year there were only a few mines which had not completed their arrangements for cyaniding their tailings.

The following shows the quantity of ore crushed, and the quantity of tailings treated in each month of 1893:—

1893.	Tons of Ore Crushed.	Tons of Tailings Treated.
January .....	174,546	43,623.80
February .....	141,763	57,517
March .....	177,291	69,778
April .....	169,106	69,800
May .....	174,973	78,483
June .....	173,212	78,828
July .....	186,216	93,819
August .....	201,391	107,586
September .....	192,858	113,217
October .....	201,141	123,513
November .....	201,939	139,132
December .....	210,168	136,900
	2,263,794	1,112,196.80

If, therefore, instead of calculating the consumption of cyanide on the tailings treated in the whole of last year, the figure for December alone be taken, we find that the 136,900 tons of tailings represent, at the above average of 2 lb., about 120 tons of cyanide for the month, or at the rate of about 1,500 tons a year.

Bearing in mind that, as we have said, the tailings obtained represent 55 per cent. to 60 per cent. of the ore crushed, it will be seen on examining the relative proportions in the above two columns that in the beginning of the year, when a number of mines were not yet in a position to use the cyanide process, the quantity of tailings treated fell considerably below this percentage. The figures for the last two months of the year show that the quantity of tailings treated was more than 60 per cent. of the ore crushed.

This is due to the fact that a number of the companies have tailings which accumulated in the settling dams prior to the erection of their cyanide plant, and are now working off these old tailings.

The chief reasons why the consumption of cyanide in the tanks is so enormously in excess of that which is theoretically necessary are :—

*Firstly.*—That the tailings contain finely divided pyrites. The action of the air on this in the settling tanks causes the tailings to become acid.

The action of ferric and ferrous sulphates upon cyanide (in acid tailings) is probably to form some of the Prussian blues.

This acidity has been remedied by using alkali; formerly lime-water was used; now, however, caustic soda seems to be preferred, most works using about  $\frac{1}{2}$  lb. of caustic soda to the ton of tailings. But although less than in acid solutions the pyrites present still consumes a good deal of cyanide, with formation of iron prussiates.

*Secondly.*—That carbonic acid is absorbed from the atmosphere and produces the following reaction—

whereby volatile prussic acid is formed

*Thirdly.*—That a good deal of cyanide remains mixed with the closely packed, to some extent, porous particles of ore in the tanks.

I may here remark that I was exceedingly struck by the large quantities of tailings which accumulate after treatment, and lie about in mounds all over the place. These still contain a good deal of cyanide, which, of course, is washed away by the rains, which are torrential in the rainy season, and a good deal gradually decomposes through the action of the air. There must, however, be a good deal of prussic acid formed, and this, one would think, might possibly do some harm; in addition to this the frequent high winds whirl the dust to a tremendous height, and are bound to carry a large quantity of this poisonous material into the town. Up to the present, however, no inconvenience has been felt from this.

In the works no ill-effects have been experienced from the prussic acid which escapes from the tanks, the odour of which is clearly perceptible, and with the exception of two kathirs, who, some considerable time ago, drank some of the water flowing from the cyanide works, I have been told that there has been no death due to cyanide. Occasionally a cow fancies the light brown liquid, and of course meets an untimely end.

A number of suggestions have been made and patents obtained for reducing the quantity of cyanide used, but I know of none (except the addition of caustic soda) which has, so far, been adopted.

When the cyanide liquors have left the tanks they run over the zinc boxes, as already mentioned. The zinc must be placed in the boxes in such a manner that, while not retarding the flow of the solution, it will cause the liquor to meet as much zinc surface as possible. The liquor runs through several successive boxes, but by far the largest amount of gold is precipitated in the first two. From the boxes the liquor runs into the snags, is there brought up to strength, and used over again.

With time the zinc all breaks down. The zinc boxes are emptied twice a month. Such zinc shavings as still remain are thoroughly washed with water, and the gold precipitate passes through the coarse retaining sieves on which the zinc shavings rest in the zinc boxes; these retain the zinc shavings which have not been decomposed. The heavier precipitate, or "gold slime" as it is called, remains on a filter placed beneath the sieve. At some mines the finer slime is filter pressed. All the slimes are then collected in basins and dried. These gold slimes contain a great deal of zinc and lead, also small quantities of silver, copper, traces of arsenic, alumina, and cobalt. In addition to this they contain potassic zinc ferrocyanide, zinc cyanide, zinc sulphide, ferrocyanide of iron, potassium carbonate, carbonate of lime, and in addition thereto ferric oxide and silica, some of which always escape from the tanks through the filters.

This material is calcined in order to oxidize the base metals and decompose the cyanides. The carbonic acid and ammonia formed escape.

The calcined oxidized material is melted with carbonate of soda, borax, and fluor spar, used in about the following proportions :—

	Parts.
Calcined slimes .....	82.0
Carbonate of soda .....	8.0
Borax .....	5.0
Fluor spar .....	4.0
	<hr/> 100.0

and a final covering of borax is given to the contents of the pot.

When thoroughly melted the contents are poured into conical moulds, the gold settling at the bottom. When cold, the gold is broken away from the slag, the pieces collected, and then melted again to be cast into ingots.

This gold runs from 750 to 780 fine. It contains a little silver, but its low quality is due chiefly to the presence of lead from the commercial zinc, and it contains zinc, copper, and other impurities in varying quantities.

Of course, the more thoroughly the calcining is done, the better the gold, but as in any case it has to pass through the refiners' hands before it is fit for use in the arts or at any mint, no special care is, as a rule, taken to improve this gold. It may be interesting to remark here that for the month of December 1893 the cyanide gold represented 37,451 oz. out of a total of 141,085, so that, approximately, 25 per cent. of the gold produced was cyanide gold.

The sumps are cleaned out from time to time and cleared of the clayey brown deposit which settles in them. This deposit is formed by the action of the potassic zinc cyanide formed in the boxes on potassio ferrous ferrocyanide in the presence of air and alkali.

Curious to say, this deposit is found to contain some gold.

The calculation of the cost of the cyanide process, as carried out on the Randt, must depend to a certain extent on the manner in which general expenses and depreciation are distributed over the various sections of the treatment, and the mines which work very large quantities must necessarily work cheaper than the smaller concerns.

I have found that generally about 6s. (exclusive of royalty) per ton of tailings is taken as the cost of cyaniding. This is borne out by the following statement of the cost of cyaniding contained in the report of the Robinson mine for 1893, which has been published in the March number of the South African Mining Journal :—

	Cost per Ton.			
	£	s.	d.	s.
Wages (whites and natives, including food) .....	3,496	11	8	1 2 81
General supplies (stores, assay material, &c.) .....	1,408	9	1	0 6 12
Fuel .....	1,204	19	9	0 5 24
Cyanide, 61,431 lb. = 1.16 lb. per ton. ....	5,563	0	2	2 0 19
Zinc, 12,521 lb. = 0.23 lb. per ton. ....	269	4	3	0 1 13
Contractor (filling and discharging vats) .....	4,325	12	2	1 6 81
Royalty .....	3,768	1	1	1 4 38
	19,036	18	2	7 2 68
Tons of tailings treated .....	55,230	tons (each 2000 lb.)		
Fine gold contained in above ..	21,180	oz.		
Fine gold extracted from above ..	13,872	oz.		
Extraction .....	68.7	per cent.		
Bullion returned .....	17,921	20 oz.		

One of the very largest mines, which is working about four times the quantity of tailings which the Robinson mine treated in 1893, claims, I understand, to be able to work the cyanide process for 4s. 9d. per ton, exclusive of royalty.

The owners of the MacArthur Forrest patent are, under their various agreements with the mines, receiving royalties which vary from  $7\frac{1}{2}$  to 10 per cent. of the value of the gold

obtained by the cyanide process. I have heard their present income from the Witwatersrandt estimated at from 75,000*l.* to 100,000*l.* per annum.

Some of the mines under their licence are bound for a certain period to take all their cyanide from the patentees, *i.e.*, The South African Gold Recovery Company.

It is quite natural that under these circumstances many are trying to find methods to supersede the MacArthur Forrester process, and inventors seem, till now, to have directed their attention chiefly to finding some other cheap method of precipitating the gold out of the cyanide solution.

The zinc method has the disadvantage of wasting a considerable amount of cyanide through the formation of the zinc salts, and the liquor, which is used over again, is when brought up to strength less effective than fresh liquor, through the presence of the zinc salts and impurities. On the other hand zinc is cheap, and it is easily separated from the gold.

I have seen the new process patented by Messrs. Siemens and Halske, whose representative, Dr. von Gerret, was working at the Randt Central Ore Reduction Company's works. They precipitate the gold out of the cyanide liquor by means of electricity, using iron as + electrode and thin lead foil as - electrode. The gold and silver is deposited on the lead, whilst the cyanide is deposited on the iron, and there forms Prussian blue. The iron is coated with a special material, which causes the Prussian blue to adhere to it instead of floating in a flocculent condition in the liquor, as it otherwise would. This Prussian blue is, by treatment with carbonate of potash, converted into cyanide.

The gold and silver are separated from the lead foil by cupellation.

It is claimed that the cost of this process is about the same as that now in use, with the advantage of the regained cyanide, in addition to which the liquor after treatment is purer than the liquor which has been through the zinc boxes.

Dr. von Gerret was working with 10 volts, and using about 10 amperes per ton of ore. I have since learned that any tension over 6 volts decomposes the cyanide to some extent. As far as I am aware the process has not yet been introduced at any of the mines.

Just as I was leaving, Mr. André arrived at Johannesburg, from the Gold und Silber Scheide Anstalt at Frankfurt, to try a new process, according to which the gold is precipitated from the cyanide liquor by means of aluminium.

I have mentioned that opinions are very divided as to the utility of concentrating, as, after all, only 3 per cent. of the ore is recovered; some therefore think that these concentrates are best left with the tailings and treated together with them by the cyanide process.

I have heard it stated, on the one hand, that when concentrates are treated by the cyanide process the extraction is practically nil, because the cyanide will not attack the gold which is finely distributed between the pyrites crystals; whilst others have told me that they have been able to obtain 70 and even 75 per cent. extraction.

Some mines are being worked without concentration, or by what is termed the direct method. I have seen the arrangement at one of the mines thus worked.

When the pulp flows off the amalgamating copper plates it runs through wooden gutters, but instead of falling on to concentrators it is led into a hydraulic separator—a kind of Spitzkasten—where the battery slimes are separated from the sand. The slimes are run to waste and the sands are directed into the tanks, and there treated with weak cyanide solution, *viz.*:—0.32 three times, in contact for 12 hours each time; 0.15 once, in contact for 12 hours; 0.08 once, in contact for 12 hours, and lastly the sands are washed out with water. Although the sands have not been exposed to the air to the same extent as the tailings which have settled in the dams they are found to be acid, and about  $\frac{1}{2}$  lb. of caustic soda per ton of sands treated is used.

Here, again, the slimes have to be separated out, and they represent about 40 per cent. of the ore crushed, and contain about 1 dwt. gold to the ton. The reason why these slimes cannot be left with the sands is that it is impossible to get the liquor to percolate, the slimes forming a mud which clogs the settling sands and stops the flow,

although in the more recent works vacuum pumps are used to assist percolation. The difficulty in the way of treating the slimes therefore, either with the sands or tailings or separately, is a mechanical one.

I have heard most varied statements as to the yield obtained by the cyanide treatment. I understand that the Gold Recovery (MacArthur Forrester) Company claim an average extraction of 70 per cent. Some have told me that they have obtained as much as 75 per cent., while others say they only get 60 per cent. Then, again, I have heard that the percentage of extraction is very unreliable, and that whilst it may be 70 per cent. one month it may fall to 50 per cent. the next. Of course these calculations depend upon the assays made, and it is very difficult to draw a reliable average sample, and the conditions vary in the different mines.

In the returns issued by the Chamber of Mines the average yield per ton is given, but not the assay value, so that no reliable figures are obtainable.

The direct method has the advantage that the ore is not handled as much as in the other, thus avoiding the loss which always occurs in handling large quantities. Moreover, the expensive chlorination process is avoided, and it is a matter of calculation whether the lesser yield is more than compensated by the difference in cost of treatment.

The total extraction at the mines from all sources is about 90 per cent. of the assay value. The average yield for 1893 was 14 dwt. to the ton of ore treated, which is equal to about 15  $\frac{1}{2}$  dwt. assay value.

I have endeavoured in the foregoing to describe what I have seen, and to lay before you the information I have gathered whilst in the Transvaal and since my return. There can be no doubt that a gigantic industry has sprung up in a very short time, and that all the elements are there for further development. But, as you will have seen, there is in addition to the question of mining, *i.e.*, beyond the judicious exploitation of the reefs, and economical underground working, a number of factors which, taken together, can only be described as an extensive chemical industry. Besides the mine properly so called, there are works which can compare to some of our large factories, and here, as in all other industries, large works must necessarily, through the distribution of expense over larger quantities, work cheaper than the smaller ones.

Management and technical skill must likewise contribute largely to the success of any one individual undertaking; and, quite apart from the value of the property, concerns may succeed or fail from other causes. This gold industry, although subject in many respects to the same vicissitudes as other industrial enterprises, has, however, over all others, the great advantage that there is an unlimited market, and a constant value for the finished product when obtained.

#### DISCUSSION.

The CHAIRMAN said Mr. de Mosenthal had succeeded in giving in the short space of an hour and a half a valuable summary of his observations, which must have been very carefully made, of a very important industry, one which a few years ago could have had no existence, because people would not have known then how to conduct these large operations, handling enormous masses of material to recover what was after all an exceedingly small percentage of a valuable constituent therein.

Mr. MACARTHUR said that it was now quite two years since he left the Randt and came home, and in that period there had been a tremendous development in the mechanical details of the processes used, and not only so, but the chemistry of the subject had been much more studied. What struck him as a chemist was that within the last few years chemistry had been taking its proper place in the production of gold. Hitherto the extraction of gold had been left rather unfairly in the hands of engineers. Very few chemists had drifted into that industry, but it was now being benefited by the chemical skill which was expended on it, and evidently this was only a beginning. As years passed on in the Randt and else-

where, he had no doubt they would be able to bring out the last 2 or 3 dwt. of the gold by the combined influence of chemical and engineering skill.

Mr. H. LOUIS, said that it was about seven years since he milled any stuff on the Randt, and it seemed to him that the industry had made most extraordinary strides since then. It really seemed almost incredible to him that these enormous works could have been raised up within the last few years. When he was there the only permanent building on the whole of this enormous goldfield was a little canvas canteen about 10 feet square. He slept with about 12 men under a waggon-tilt under blankets, and the canteen was the sole representative of the enormous buildings which had sprung up in 10 years. Then he saw nothing but the surface reef, the thoroughly oxidised reef as it was called, and he should like to ask a question with regard to that. He was rather inclined to differ from Mr. de Mosenthal if he understood him correctly to say that the various colours he saw through the microscope of the different kinds of gold were due to alloys with various metals. He had been working on this question for some time, and had come to the very strong opinion—he could not call it conviction—that gold was certainly dimorphous and probably polymorphous, and that these different colours were due to absolutely different forms of gold. The question was a most complicated one, and had a very serious bearing on the question of gold-milling. He proved to his own satisfaction, and he believed he was one of the first to find it out, that certain forms of gold, under certain conditions of deposition, were not attacked at all by mercury. It could be precipitated in such a form that it would not be attacked by mercury at all. Much of this Randt gold was highly crystalline, and there was some evidence to show that it was deposited *in situ*. It was not ordinary river gravel, but gravel into which the gold had percolated and been deposited there. The fact of the gold being thrown down from solution led him *a priori* to suppose it would be under conditions in which it would resist amalgamation, and that was exactly what took place. A certain proportion of the Randt gold was amalgamable, and a certain proportion was not, and he entertained a strong opinion that that was due to its polymorphous condition, and Mr. de Mosenthal's experience of the different colours of the gold seemed to him to point in that direction. He should like to ask if he understood the author correctly when he said that these so-called reefs maintained the same angle all the way down. His impression was, from the faint surface scratching which had only been carried out in his day, that the reef showed a tendency to flatten, as the subsequent borings seemed to prove. He had the idea that they had discovered the opposite rim of the basin, but that was a point he could not say he knew much about, as he was not there from the very beginning, but he should like some further information on that subject. After a good many years' gold-milling in many parts of the world, including America, he thought an extraction by amalgamation of 80 per cent. to 90 per cent. was thoroughly exceptional; he himself had never seen it, and he should say wherever they got 75 per cent. from milling gold in the ordinary run of stuff, they were doing remarkably good amalgamating; he knew very few instances where it was exceeded. He might also suggest that the excess of copper in the gold doubtless came from the copper plates themselves. It was his invariable experience that when one ran fresh plates one found more copper than after they had been running some time. In connection with that he would like to ask whether electro-plated plates were not being used on the Randt. In the States of America the plates were nearly all electro-silvered before amalgamation. There was an immense deal to be said on that subject which he could not enter into then. With regard to the cyanide process he should like to ask whether it was an actual fact that pure zinc would replace gold in a solution of auro-potassic cyanide, or was it a much more complicated question? His own impression was that, if you dissolved gold in a cyanide solution and put pure zinc in, you would not get any precipitation at all. He believed the thing was much more complicated than was thought. In conclusion, he could not help pointing out that the diagram of a 10-stamp

mill was misleading, inasmuch as it showed the tops of the dies 2 or 3 ins. above the string frames. Such a thing could not run for five minutes.

Mr. BOVERTON REDWOOD said he was ignorant both of the chemistry and the mechanical details of this subject, but he was sure he would be supported by everyone in moving a very cordial vote of thanks to Mr. de Mosenthal for his most interesting paper. He might say that he now fully understood for the first time how it was that with these complicated processes one might have exceedingly rich gold-bearing properties, which nevertheless would be pecuniarily unsuccessful. It was quite obvious that there was great room for mismanagement, and, on the contrary, opportunity for very considerable improvement, in organisation and in the processes of extraction through the application of chemical talent and engineering skill.

Mr. WATSON SMITH very heartily seconded the vote of thanks. In doing so he should like to call attention to a most interesting communication which had been sent to him by Dr. George Gore, F.R.S., of Birmingham (see page 428). In a series of experiments made recently by Dr. Gore on the action of finely-divided silica upon solutions of various salts, acids, and alkalis, this authority had specially experimented with cyanides of potassium and sodium. In the case of most of the substances in solution, Dr. Gore found that if the solution were shaken up with the silica (of course in comparatively large bulk compared to the weight of dissolved substance) and then allowed to settle, and the supernatant liquid subsequently examined, a considerable quantity of dissolved substance or salts would be found to have disappeared. If the supernatant liquor were poured off, and that left behind and which had soaked into the silica examined, it would be found to have gained in dissolved substance. Indeed, Dr. Gore suggested that finely-divided silica would prove a useful means for abstracting small quantities of iodine from weak solutions thereof, the sand being subsequently heated to set free and recover the iodine. That gave an idea of the extent to which this singular action went on. Turning to cyanides of potassium and sodium, he said the effects of silica upon weak solutions of cyanide of potassium indicated that the great loss of the latter substance in the commercial process of extracting gold and silver from powdered quartz was largely due to the "adhesion" of that salt to the silica. He remembered when, a few years ago, he, in conjunction with Mr. Graham Young, read a paper on experiments tried on the laboratory scale with the MacArthur-Forrest process, that Mr. MacArthur drew their attention in the discussion to the importance of washing the ground quartz with water after the cyanide treatment. Such a washing in good filter-presses was probably the means of overcoming the difficulty referred to in so interesting and striking a way by Dr. Gore. Nevertheless there was no doubt that were it not for this remarkable property of fine silica, mere filter-pressing would then represent what now filter-pressing plus a good deal of washing combined represented, or, in other words, a larger mass of extremely weak wash-liquors than would have been necessary had no such property existed in silica. Other inert solids in powder were also tested, but finely-divided silica exhibited this property of "adhesion" in the most marked degree.

Mr. SUTHERLAND said he should like to add a word if only to place on record his appreciation of what Mr. de Mosenthal had done. He had the pleasure of seeing this paper a few weeks ago, and was struck at his anxiety in endeavouring to bring before a meeting in one evening so large a subject, but he had done so most successfully, and had been able to focus it in a way which had greatly interested them all. It occurred to him that it would be a great advantage to the London Section if they had a few more popular papers of this kind upon certain subjects, as the members would then better appreciate special papers following afterwards on particular points, as he hoped they might in this case have separate papers hereafter throwing more light on the chlorination and cyanide processes. It was not many years ago since a Randt man arranged to use a portion of his laboratory for the purpose of

investigating a process for the extraction of gold from solution in cyanide of potassium. He was not quite so successful as he had hoped in depositing the gold from this solution, and after a few weeks asked for assistance, generously offering in return a share in the patent. It appeared that his process consisted in the addition of sulphuric acid, and he obtained a very large precipitate of gold, though after evaporating to dryness and fusing he did not obtain anything like the whole of his gold. It was not until that fused salt, after being dissolved and refiltered, was again evaporated and fused with nitrate of potassium that he got the whole of his gold out. He only mentioned that as a popular illustration of the difficulty of precipitating in the ordinary way.

MR. DE MOSENTHAL, in reply, said that Mr. MacArthur had made a reference to chemical skill and to the position which chemists now might occupy with regard to the gold-mining industry in South Africa. He had himself been struck by the secondary positions given to chemists there, and the fact that in South Africa, as in many countries, the so-called practical men were placed in charge. A man who had worked underground for many years and was no doubt very competent as to the best manner of exploiting a reef, was thought also the best man to conduct the works for the extraction of the gold. It was the same all over the world, and it would be many years before the prejudice would be entirely overcome. Nevertheless, he believed that the chemists on the Rand were making headway, and he was sure that the more they did so the better it would be for the industry.

In reply to Mr. Henry Louis, having regard to the large amount of material he had to deal with in a short space of time, it was quite impossible for him to go into details. As to the microscopic appearance of gold extracted from pyrites, he saw crystalline structure in some of the specks, while others were distinctly amorphous. He considered that the various colours shown in gold by transmitted light were due to a great extent to its physical condition, and that gold is polymorphous has been shown repeatedly. Some maintained, on the other hand, that the different appearances of gold were frequently due to the particles being coated with impurities, whilst others maintained that we were in presence of alloys, the gold containing minute traces of other metals. It was well known that if gold be dissolved in *aqua regia* and precipitated therefrom by sulphurous acid it appeared granular under the microscope, while the gold which had been separated from the mercury by treating gold amalgam with nitric acid, appeared as octohedral crystals. With regard to the high extraction of 80 per cent. over the plates, he had this information from someone who had worked practically in Venezuela and could only give it at second hand. As for the deep levels, time had only allowed him to give a very short description, and he was perfectly aware that it had been found that the reefs flattened somewhat in depth, as in the deep-level borings the reef had invariably been struck 100 feet or more nearer the surface than at first calculated. The substitution of zinc for the gold in the double salt ( $\text{KAuCl}_2$ ) when the precipitation first begins in the zinc boxes seemed excessively probable, and Mr. Louis could, after the meeting, see both the double salts, samples of which had been prepared for him by Mr. Bettel.

The CHAIRMAN said perhaps it was because he was a chemist, but he had a strong impression that an engineer's chemistry was not nearly so good as a chemist's engineering; and especially when a chemical process was concerned it was better to let the chemist be his own engineer. It was very important in these days that a chemist should be something of an engineer.

April 6th, 1894.

MR. IVAN LEVINSTEIN IN THE CHAIR.

### COMPARATIVE RESULTS OF SOME MODERN SYSTEMS OF SEWAGE TREATMENT.

BY W. NAYLOR, F.C.S.

SINCE the formation of county councils in the year 1888, the prevention of rivers' pollution has received a considerably increased amount of attention, due to the fact that the administration of the Rivers Pollution Prevention Acts is now in the hands of bodies not themselves in default. Moreover, the local authority having administration of the Act is not unduly influenced in cases of manufacturing pollution owing to the preponderance of representatives directly engaged in manufactures. The action of county councils, therefore, in this matter is distinctly towards broad uniformity. And this action, whether it be commendable or otherwise, has resulted in numerous schemes of sewage treatment and various descriptions of plant being placed upon the market for dealing with all kinds of noxious and polluting liquids.

I purpose to-night dealing with the question of sewage treatment only. Manufacturers, as men of business, I presume, may be safely left to manage their own affairs, although I would hardly venture to say the same concerning local authorities on this point. It certainly may appear a bold statement to make, but "by their fruits shall ye know them." In fact, it will probably be admitted that the members of local authorities are elected upon broader and indeed more honourable grounds than an intimate knowledge of sewage treatment, that they represent the ratepayers' interests generally, and that upon technical points they should consult specialists. Unfortunately my experience is that upon matters appertaining to the treatment of sewage specialists are very rarely consulted, and even when they are their advice is considered after, and a long way after, the question of £ s. d.

In the larger corporations the matter is left to a sewerage committee, not universally formed of the most influential and intellectual councillors. Of course, exceptions will at once occur to all of us here, but broadly speaking a sewerage committee is not a committee like the finance, library, and public works committees, and is often relegated to the "practical men" on the council. Now, to these practical men, so called, nothing in the world seems so simple as the proper treatment of sewage. Each one holds in his bosom a scheme destined to solve this complicated

problem and to save the impoverished ratepayers' money. But while this committee of practical men is in solemn conclave assembled, one of the kid-gloved councillors stealthily creeps in with a pamphlet, and from that time forward each in his turn arms himself with a pamphlet defying all comers, and a terrible war is waged on the various systems. It is just this state of things which prompts me to offer the following results, and to attempt roughly to delineate a sort of table from which perhaps a uniform line of action may be suggested. In each town, so far as my experience goes, the discussions on sewage treatment seem to be conducted on altogether different lines. Analyses are put forth copied from various printed pamphlets which I hesitate not to say are absolutely worthless. I lay the results to follow before you, therefore, holding a brief from no one. The samples were taken personally, and not after due notice, but on surprise visits.

At the outset I may take it that however divided the opinion may be regarding the treatment of organic matter in solution in domestic sewage, all suspended matter can be, and ought to be, eliminated by either filtration (in the case of broad irrigation), subsidence, or precipitation. The dissolved impurities or organic matters in solution must claim our common attention as objectionable. They are objected to on the following grounds:—

1. That they decompose, so causing a nuisance.
2. That they are liable to become the home at d breeding-place of disease-producing germs. It has been proved\* that the organic matter in sewage is *per se* harmless except in so far as it robs natural streams of dissolved oxygen, and this only to a very slight extent.†

The micro-organisms present, however, affect it in so much that they cause its decomposition‡ and on this fact certain schemes of sewage treatment mainly depend, viz., the sterilisation systems.

In making a table of the various systems, the plainest line of demarcation can be drawn between sterilisation systems and all others. While the sterilisation systems attack the organism in the open field, so to speak, with the object of killing it outright, all others aim at depriving it of food and so starving it out. In fact, the two systems may be compared to a pitched battle on the one hand and a siege on the other.

But to my mind it has always appeared useless to attack and kill organisms and yet not destroy their food, just as it would be useless to attack and destroy a garrison of soldiers and yet allow the supply of provisions to pass on to the enemy's reinforcements.

One of the earliest systems of sterilisation was the "Amines" system, in which sterilisation is claimed to be brought about by a gas termed aminol. It is said to be generated by trimethylamine and any alkali.

In practice the trimethylamine is added as a certain proportion of herring brine, and the alkali as caustic lime. The evolution of the aminol gas is in exceedingly small quantities, in fact imperceptible. It is claimed, however, that, small as it is, the quantity is quite sufficient to destroy all forms of germ life, and I do not for a moment intend to dispute this. Whether from a bacteriological point of view the effluent is dead or otherwise, I am not prepared to say, but this much is certain, that the organic matter in solution is not appreciably diminished. The effect of this treatment on the Wolverhampton sewage, so far as the organic matter in solution is concerned, is shown in the results given elsewhere, Nos. 1 and 2.

It is claimed by advocates of the sterilisation systems that the decomposition of the organic matter is arrested permanently, since the atmosphere contains only non-pathogenic germs, which exude organic matter as inert or inorganic. This argument, however, cannot stand, as pathogenic ferments can and have been discovered in natural waters.§ They have also been discovered in the atmosphere. As proof of this, one has only to place a vessel containing organic matter, such as beef tea, in the open atmosphere in summer weather, when it will soon begin to decompose and give off most disgusting smells.

Further, I will venture to say that there are very few rivers in England which do not receive crude sewage in some shape or form; and the only condition under which sterilisation systems can approach success is in cases where the effluent has but a short distance to run before being lost.

Another and more recent form of sterilisation system is the "Bacillite." In this case the sewage is intimately mixed with the vapour of a mixture of carbolic acid, cresylic acid, and pine-oil extract.

These three compounds are introduced by means of a small donkey pump into a boiler at high pressure; then as vapour they are introduced into the main outfall sewer by means of a battery of injectors. It is claimed that in the form of vapour the germicidal efficiency is increased 200-fold. Pine-oil extract, it is claimed, only acts as an oxidising agent.

Apart from the sterilisation, the effluent at Kettering, where half a million gallons per day are treated by this method, contained on the 27th of January 1894, 0.6 part per 100,000 albuminoid ammonia.

The "Hermite" process, I think, is the latest which claims to sterilise sewage. Here the sewage is mixed with a certain proportion of sea water, which has previously undergone electrolytic decomposition, and is therefore highly charged with oxides of chlorine, said to be powerful disinfectants. The experiments at Worthing are not yet completed, and it would be premature to say at present more than this, that a sample drawn after treatment gave 1.38 parts per 10,000 albuminoid ammonia, and this at any rate is a consideration which the inventor does not profess to concern himself with.

Dr. Kelly, medical officer of health for Worthing and combined sanitary district of West Sussex, after making a trial has reported: "Since there is no instantaneous decomposition of faecal matter and no sterilisation of sewage, I am of opinion that the process, as far as the late trials have gone, has failed to produce the results which are claimed for it by its inventor."

It must be admitted that the effect of a current of electricity passing through water containing organisms is to kill them, granting the current is of sufficient electro-motive force (about five volts), but its effects upon spores have not yet been demonstrated.

It has been proved that the—

	Volts,
<i>Bacillus tuberculis</i> is killed by an electro-motive force of 2.16	
<i>Bacterium lactis</i> " " " "	2.26
" <i>aceti</i> " " " "	3.24
" <i>allii</i> " " " "	3.3
<i>Bacillus subtilis</i> " " " "	2.72

Granting so much then for the electrical, so far as sterilisation is concerned, I can only refer to the Salford trials for the result of the treatment upon dissolved organic matter, for I am not aware that at any place it has been permanently adopted.

The albuminoid ammonia in the effluent was at times:—

0.25 part per 100,000.
0.17 " "
0.13 " "
0.11 " "
0.17 " "
0.10 " "
0.11 " "
0.11 " "
0.13 " "
0.092 " "

The results are after filtration through sand.

These figures need no comment, but speak for themselves as satisfactory; and as this is the first system mentioned as satisfactory, the next matter of importance is the cost. Various systems of treatment would occur to many people as capable of giving good effluents in which the cost is

\* Emmerich, "Zeitschrift für Biologie," Vol. XIV., p. 563.

† Rivers Pollution Commissioners' Report, 1868—1872.

‡ A. B. Griffiths, "Micro-organisms," pp. 87 and 40.

§ A. B. Griffiths, "Micro-organisms," pp. 45, 47, and 49.

prohibitive—distillation for instance. Now the cost of the electrical treatment at Salford was based upon:—

Estimated horse-power (labour and coal).....	£ 3,700
Consumption of iron.....	4,500
Depreciation and interest on capital.....	3,525
	<hr/> 11,725

This is apart from sludge-pressing (2,070*l.*).

It was the most expensive of the systems tried. One-third of the cost of treatment (exclusive of pressing, the cost of which differed very little from the next higher, the International) was for indicated horse-power, and this was based upon a run of 132½ hours. Now, high as this cost works out, it is probable that in lengthy practice it would work out higher.

The efficiency of the treatment, or, more properly, the extent of purification, depends upon the amount of current passed through the sewage. We may take it that in the electrolysis of sewage (as in anything else) the amount of chemical decomposition is directly proportional to the amount of passing current, and that a given quantity of sewage requires a given quantity of current for a given period of time.

This current has to be passed between the electrodes through the intervening sewage. This intervening sewage offers a certain amount of resistance, the resistance following Ohm's law,† in liquids as in solids, viz., "the current varies directly as the electro-motive force, and inversely as the resistance."

It follows, therefore, that the greater the distance between the plates, the less the current for a given electro-motive force, or the greater the distance between the plates, the higher must be the electro-motive force to cause an unvarying current. As the plates are oxidised away, and the distance between them is augmented, the speed of the dynamos must be increased, and the engines run quicker, and more coal and labour consumed to ensure the current in quantum suff.

At Salford the plates were ½ in. thick, and the intervening spaces ½ in. initially. Finally the spaces would be 1½ ins., and the initial electro-motive force to the final as 5:9; and the initial to the final cost of current would follow the same ratio, except in so far as large quantities of power can be generated more cheaply than small, compared unit with unit.

A valid objection to this reasoning may be advanced—that a point would be found in practice at which it would be cheaper to renew the plates than to pass current through so great a space; but in that case the remaining plates should have been weighed in as a loss of iron, and cost calculated upon the average current through the whole life of the plate, not upon a run of 132½ hours.

I have mentioned this objection to the test before, and was met with the reply that in practice the electro-motive force required is constant. Well, if it is so, surely a fact of such importance, a fact which goes in the face of well-established theory throughout, and all other known practice, should be accounted for and regarded as an important discovery, and not allowed to rest upon *the ipse dixit* of any one.

**Precipitation.**—Concerning the comparative merits of continuous-flow or quiescent tanks, nothing here need be said more than that the choice depends upon local conditions. Where land is scarce, small quiescent tanks give as good results as large continuous-flow tanks, but require more labour, the extra cost of which has to be compared with the interest on capital sunk for extra land.

Continuous tanks could be used at a lower level, except that the sludge must be relieved of the supernatant liquor before emptying, which necessitates pumping. To obviate this difficulty two continuous-flow tanks have been lately brought out, in one of which, the "Ives," the sludge is pumped from a conical-shaped bottom while the tank is in operation.

The principle is a good one, which sooner or later will generally be adopted. The objections to it are:

1. That sludge immediately above the outlet *only* is pumped out, and is followed by the sewage, which soon makes the sludge thin.

2. The sludge remaining on the sides decomposes, so affecting the effluent. The results of the working of this tank at Tamworth are shown in analyses 9 and 10.

A great improvement on this is the Candy Tank, which has a flat bottom, and from which the sludge is siphoned through a revolving arm. The tank can be worked with a foot head to 10 times its capacity per 24 hours, and emptied while in use. A result of the working is shown in analyses Nos. 11 and 12.

Both tanks are fed at the bottom under a bonnet with a dip pipe.

#### Oxidation Processes.

1. **Precipitants.**—Much has been written and said concerning oxidation by precipitants—but very little done, and I fancy the advantages of ferric salts over ferrous have been very much over-rated. It is no doubt truly contended that ferrous salts are reducing, and ferric salts oxidising agents, but this much is certain, that no ferric salts have yet been put into use which will produce a satisfactory effluent alone, and that much ought to be generally known.

In considering the equations—

we must bear in mind that the ferric hydrate is only sparingly soluble in water. That which is suspended undergoes no such chemical change, as evidenced by the permanency of the bluish-green and red colours. Further, the samples numbered 14 to 23 show the oxidising effects of iron salts to be slight in any case, and that the value of these salts is in their power of precipitating suspended matter more than anything else. It occurs to me that oxidation is more easily brought through the agency of filters than precipitants, and more attention might be paid to these with good result. By this I do not mean oxidation in filters by means of the oxidising action of ferric hydrate in the filter, which hydrate is alternately in the ferric and ferrous state, as it is claimed to be in the case of the Kremmolite precipitant. The effect of such action is shown not to be very startling by the result No. 22. The filter I refer to more particularly is a filter where oxidation is brought about both by direct oxidation and nitrification.

The great amount of attention paid just now to oxidising precipitants suggests the idea of a dynamo tender running short of current devoting all his attention to the exact setting of brushes, oiling, &c., instead of running the engine faster, or decreasing the resistance to the current. *His attention is directed to the wrong point.*

2. **Direct Oxidation by Filters.**—The three specially prepared filtering materials which I had hoped to bring before you, and in fact the only three of whose existence I am aware, were polarite, porous carbon, and Bell's magnetone. I regret that I am not able to do this in the way I desired.

I wrote asking the porous carbon patentees the nearest point to Preston at which it could be seen in use, and was advised that such a point was Richmond. Upon writing to the engineer in charge of Richmond works, however, he informed me that only a portion of the filtering area contained porous carbon, that that was not in constant use, that certain days were set apart for visitors, and that I should not be allowed to take samples without previously making an appointment. It is needless for me to state therefore that samples were not drawn, although I applied for and was supplied with a sample of the porous carbon.

Bishop Auckland was the point to which I was directed for a sample of sewage treated by "Bell's Magnetone," and here also I was unable to get a sample of effluent owing to personal reasons. A sample of the Magnetone, although applied for on the 20th ult., is only just to hand. Concerning this process therefore I will say nothing further.

\* Reports of Salford trials.

† Geor., "Electro-chemistry," p. 9.

‡ Journal of the Chem. Society, Vol. X., p. 203.

The action of polarite and porous carbon I take to be one of direct oxidation, due to the exceedingly fine cellular construction of the materials. The microscopic pores contain oxygen, which acts in the same manner as occluded air in spongy platinum. The pores in polarite, however, as seen under the microscope, are much finer than in porous carbon. Moreover, a jet of hydrogen passed through the two substances raised the temperature of polarite much more readily and to a higher point than it did in the case of porous carbon.

Further, if equal quantities of solution of  $\text{SH}_2$  be passed through equal filtering areas of polarite and porous carbon, that passed through the former will give a much denser precipitate with  $\text{BaCl}_2$ .

Again, Padibam clear sewage containing 0.27 albuminoid ammonia, passed through polarite and porous carbon, gave 0.11 in the one case and 0.19 in the other respectively.

Other results of polarite treatment are shown in the analyses numbered 24 and 25.

### Natural Media.

By the term "natural media" I wish to be understood those media in which oxidation is not brought about by direct oxygen contact, but by the nitrifying organisms; and I must confess at once that this, to my mind, is the best method of sewage treatment where such media can be obtained. Of course the limitation is very necessary and very wide; but at the same time I hesitate not to say that where failures have resulted they have accrued in all cases either from mismanagement or unsuitable physical conditions.

At Lincoln, for instance, where it has failed, a commencement was made with 55 acres of land. This was not under-drained, and crude sewage put on without any attempt at precipitation. Soon after, it was found that the land had become choked, and a resort was made to subsidence tanks and draining. Then precipitation by lime, followed by lime and iron, the whole finally to be abandoned for polarite filters.

In the case of Preston, a tract of sandy land has been embanked from the Ribble estuary (600 acres in extent), portions of which are from time to time literally submerged with sewage. The land is not under-drained, but the sewage left to drain away wherever it may find outlets. Such outlets, however, are very scarce, for during a considerable portion of the day the farm embankment is flanked by sea-water.

The average level of the surface is 13 feet above ordnance datum, and ordinary spring tides rise to this height, the ground water rising under the farm of course with the tide. On the ebb tide the absorbed sea-water makes its way out first, then a mixture of sewage and sea-water, and finally the sewage. But at this point of time the flood tide commences and drives back the sewage to the top, and so on *ad infinitum*. On one occasion I observed about 2 or 3 feet depth of sewage on the farm, and on this, on a floating raft, workmen were engaged repairing the embankment.

The effluent, taken at low water, gave—

Chlorine .....	69.7 parts per 100,000
Dissolved solids .....	359.3 " "

How anyone could select such a site for a sewage farm is surely a mystery.

Other flagrant cases of inappropriate sites are Chorley, Blackrod, and Shepton Mallet (Somerset). Each of these is a farm forming a river bank. In the first case the farm has an average fall of 74 feet in its width of 1,056 feet, or about 1 in 14. Blackrod has an average fall of 130 feet in its width of 400 feet, or about 1 in 3, while Shepton Mallet, in spite of a favourably altered configuration, still has an average gradient of 1 in 6. It is needless for me to point out that the sewage in these three cases just takes a straight line for the river, which explains the figures shown in analyses 27, 28, and 29. In contradistinction to these I will instance the farms at Ormskirk and Wigan. The former is a good loamy soil, with a flat surface, is well cultivated, and not "doused" with sewage. There is sufficient acreage to the population, and the sewage is

treated in tanks as a preliminary step. At Wigan there is a farm of 270 acres now giving a good effluent. The 270 acres of flat loamy land was divided last year as follows:—

	Acre.
Mown hay.....	70
Corn.....	70
Potatoes.....	16
Turnips.....	10

About 6 acres filter beds and under 100 acres grazing.

### AMOUNTS RECEIVED FROM OTHER PLACES FOR TREATMENT OF THEIR SEWAGE.

	£
From Aspull.....	260
" Ince.....	271
" Orrell.....	195
Sewerage rate equal to 7d. in the £.	

### DETAILS FOR YEAR ended MARCH 1892.

	£	s.	d.
Sinking fund, sewers.....	101	8	9
" " farm.....	61	9	4
Interest, sewers.....	2,914	3	2
Assessment of sewer pipe.....	12	0	0

Wages. Screen chamber.....	24	4	6
" Sewerage account.....	165	10	4
Compensation.....	18	15	0
Loss on farm, year.....	1,235	15	8

These figures, together with an effluent giving off only 0.1 part per 100,000 albuminoid ammonia, speak exceedingly well for a sewage farm properly situated and well managed. But there is only one Wigan, unfortunately.

It is such figures as these that visiting deputations ought to ask for, and not figures concerning the maximum quantity of storm overflow allowed to be turned into rivers, injunctions, price obtained for sludge, number of w.c.'s, prime cost of works, &c., &c., as is frequently done.

*Artificially prepared Fermentative Oxidation Media.*—An impression has long been abroad among the local board "practical men" that coke is the proper thing through which to filter sewage.

Reason and figures are of no avail with a sewerage chairman who has set his mind on coke. It is an old-established institution, handed down from father to son, and will die hard, but die it must, for (as shown by the Nelson figures) it has no effect on dissolved organic matter at ordinary filter depths and rates of filtration. This coke, however, was pulled out and burnt during the recent coal famine, doing more good on that particular occasion than it ever did before. Its ghost, however, is now on exhibition at Baildon in the form of a "carbon" filter, *so called*.

Ashpit and privy refuse is here burnt (carbonised, it is claimed) and a filter made of the resulting ash, which is nothing but ash. This forms a sand filter, but that is all; and if of sufficient area would perhaps in time form a nitrification bed.

This is a process which at once appeals to the minds and pockets of local boards. No precipitants! no expensive filters! refuse disposed of! no pollution. The impossibility, however, of its application on a large scale must be apparent at once to any but an outsider. The sewage treated at Baildon by this process is initially very weak. Its effect upon that is a mere screening effect, as shown by the results numbered 34 to 37.

The result of a very recent system is shown in Nos. 38 and 39.

This system was the subject of two very plausible leaders in the "Engineer," which were copied pretty freely in other journals.

In fact the birth and fame of this process is the best example of that utter recklessness with which people launch into the question of sewage treatment, which I ventured to call your attention to in the hope that some definite data for the choice of a system may be suggested here. A person notices certain effects resulting from a filter through

which the sewage of *one house is passed*. These effects (not at all unusual in themselves) form the subject of leaders in a standard engineering journal, patents are taken out, and a 16-page pamphlet issued, offering a process of treatment without money and without price; which process, as seen at Toweester, is neither more nor less than a sand

and gravel filter, and not the best at that, as evidenced by the samples taken without notice.

It is just as easy for good samples to be taken by judicious preparation as it is for bad. For instance, here is a series of analyses to me as showing the effect of an "Ives" precipitation tank.

## WATER.

## COUNTY ANALYST'S LABORATORY, UNITY BUILDINGS, BIRMINGHAM.

## RESULTS OF ANALYSIS EXPRESSED IN PARTS PER 100,000.

Date of Receipt of Sample.	Description.	Total Solid Impurity.	Free Ammonia.	Organic Ammonia.	Nitrogen as Nitrates and Nitrites.	Total Combined Nitrogen.	Oxygen Absorbed in 4 Hours.
1893.							
September 5th	Samples sent by Mr. H. J. Claison, C.E., Tamworth.						
September 7th	Sewage .....	846.0	0.000	2.998	0	..	..
September 11th	Effluent from Glascoate .....	68.0	0.000	0.080	0.22	..	..

Date of Receipt of Sample.	Description.	Chlorine.	Suspended Matter.			Remarks.
			Organic.	Mineral.	Total.	
1893.						
September 5th	Samples sent by Mr. H. J. Claison, C.E., Tamworth.					
September 7th	Sewage .....	10.0	3.3.0	370.0	763.0	Very turbid. Foul odour.
September 11th	Effluent from Glascoate .....	6.1	..	..	0	Fairly clear. No suspended matter. No odour. Neutral in reaction.

These two analyses were shown to me, as they had doubtlessly been to many others, as illustrating the effect of an "Ives" precipitation tank. When, however, I pointed out that the nitrates had gone up and the chlorine gone down, which was a very unusual effect of a precipitation tank, it was courteously explained that one sample was drawn four days after the other.

The method and point of time of sampling sewages appears to me to be one of the many other things omitted from an analysis which should there find a place.

For the purpose of forming the framework of a discussion I suggest here, in conclusion, that the following rules be laid down for the efficient treatment of sewage:—

1. Suspended solids to be removed by precipitation in some form.
2. That the organic matter in solution be oxidised (directly or by means of natural nitrification).
3. That no effluent entering a natural stream or canal should give off more than 0.1 part per 100,000 albuminoid ammonia.
4. That the precipitated sludge be pressed and burnt.

## TABLE OF COMMONER SYSTEMS.

The following have been elected to fill the vacancies, and will take office in July next:—*Vice-Chairman:* J. J. Hummel. *Committee:* T. Fairley, W. Leach, A. G. Perkin, and Thorp Whitaker.

SESSION 1893-94.

May 7th:—

Mr. H. R. Procter:

"The Qualitative Recognition of Tanning Materials."

"Note on Recent Modifications in the Estimation of Tannins."

Mr. A. G. Perkin: "On a Rapid Method of Testing the Shade of Alizarin Paste."

Messrs. J. J. Hummel and H. R. Procter: "Note on an Improvement in Dyeing Leather with Basic Colours."

Meeting held at the Queen's Hotel, Leeds, on Monday, April 2nd, 1894.

PROFESSOR SMITHELLS IN THE CHAIR.

## THE TINCTORIAL PROPERTIES OF SOME INDIAN DYESTUFFS.

BY J. J. HUMMEL AND A. G. PERKIN.

### PART I.

IN these days, when the artificial colours derived from coal-tar are becoming each year more and more numerous and important, and are gradually pressing into the background the natural dyestuffs, we almost feel it necessary to give some reason why we should have selected not merely natural dyestuffs for detailed scientific and practical examination, but such as are not usually, if at all, met with in the European market. Our explanation is simply this:—It may be known to some of you that during the past few years, owing to the munificence of the Clothworkers' Company of London, a Research Laboratory has been established in connection with the Dyeing Department of the Yorkshire College, and as part of our work, we have set ourselves the task of aiding in carrying out one portion of the programme of the Imperial Institute of London, by taking up the examination of Indian dyestuffs. Many of these dyestuffs are highly spoken of, as yielding colours which possess in a marked degree the qualities of fastness to light, excellence in tone, &c. This being so it is surely desirable to test such statements by actual experiment, and if there are natural colouring matters with distinct and useful properties, it were a pity if we deliberately neglected them.

India, so rich in dyestuffs, and the birthplace of the dyeing industry, has in the past furnished us with our fastest dyestuffs, indigo, and alizarin, also our most important and interesting processes of vat and Turkey-red dyeing, and may we not still have something useful to learn from her vast resources in this domain?

Further, the starting point of the manufacture of artificial alizarin, one of the most notable discoveries of the century connected with colouring matters, was surely the Indian madder. In like manner it seems to us that by patiently investigating the colouring principles present in various natural products, especially those of India, one may meet with important new compounds, and by determining their constitution, perchance, lay the foundations of some industry like the one referred to, to be built upon by others who take up the subject where we relinquish it.

Already, among the few dyes examined by us, colouring matters, apparently new to science, have been isolated, one of which seems to possess such tinctorial properties as may possibly render the dyestuff, even in its natural condition, of commercial value.

### Chayroot or Indian Madder.

This dyestuff is the root of *Oldenlandia umbellata*, Linn., Rubiaceae. It bears a number of vernacular names, among which may be mentioned: *surbuli* (Bengali); *cherivelu*, *chiri-veru* (Telugu); *saya*, *saya-wer*, *imburai* (Tamil); &c. The name *chay-root* or *chayaver* is said to be derived from *chaya* (which fixes colours), and *ver* (root).

It is a low, spreading, bushy, biennial plant commonly met with in sandy soils in North Burma, Bengal, the Madras Presidency from Orissa southwards to Ceylon, on the Malabar coast, and indeed very generally in Southern India.

Although occurring abundantly in some parts of Bengal it is not there used as a dye, but on the Coromandel coast it is extensively cultivated in many parts, especially at Nellore and Masulipatam. The chief market is Madras, where it is sold in small bundles, the retail price being about  $\frac{1}{4}$ d. per lb. The cultivated roots are very thin, and often a yard or more in length, while those of the wild plant are shorter and thicker, being usually 10 to 12 ins. long and  $\frac{1}{2}$  in. thick, somewhat straight and stiff, tough and wiry, and with few or no lateral fibres. Contrary to our general experience in the case of madder, the wild variety is more highly esteemed, and is said to yield a fourth more colouring matter. Roots of two years' growth are preferred, but the farmer finds it more profitable to gather them at the end of the first year, when they are merely dried in the sun for a few days and tied into large bundles. When freshly gathered the roots have an orange-yellow colour, but on drying they assume a yellowish-grey hue, becoming even brownish during long storage.

The colouring principles seem to be situated almost entirely in the bark of the root. The ground root has quite an ashen-grey appearance, but on treatment with hot or even cold water a yellow extract is obtained, and with the addition of alkali the solution is of a deep red colour.

**History.**—In India chay-root has occupied somewhat the same position as a dyestuff, as the madder did many years ago in Europe. It seems to have been very commonly employed by the Hindus on the Coromandel and Malabar coasts from time immemorial, for the production of very permanent reds, purples, and blacks, on calico prepared with oil and aluminium, or iron mordants, a process analogous to, and no doubt the forerunner of Turkey-red dyeing as pursued in Europe. From the fact that the alum mordant, applied by the native calico-printers, was frequently coloured red with sapan wood, the Hindus themselves, and also some early French writers who described their processes, concluded that the chay root was merely used by the natives as a fixing or brightening agent for other colours, rather than as a dye itself. Others again have referred to it as a yellow-colouring matter, or as an astringent substance devoid of any red colour. In this manner one sought to explain why it was found impossible to make any use of a large quantity of chay-root, imported by the French East India Company in 1774. (M. Le Goux de Flaix, "Annales des Arts et Manufactures," No. 51).

Bancroft in his "Philosophy of Permanent Colours," vol. II., p. 298, states that a large quantity of chay-root was brought to England about 1803 by the East India Company. His experiments with this consignment were not very successful, and several dyers and calico-printers, to whom samples were sent, did not succeed with it, and were not disposed to adopt it. This want of success was ascribed by Bancroft to the roots having been of inferior quality or having suffered injury by age or damp. Ultimately, however, he satisfied himself by further experiments on selected samples that chay-root, in conjunction with alumina mordant, was capable of yielding on wool, linen, and cotton a red colour very similar to, both in appearance and permanency, but never exceeding, that given by madder. Calicoes printed with mordants and dyed with it had the whites less stained than with madder. Wool mordanted with tin yielded a very bright and lasting red inclined to orange. The most remarkable difference between madder and chay-root in their dyeing properties, according to Bancroft, was that with the latter and iron mordant nothing darker than drab colours could be produced either upon wool or cotton. Wool boiled with a solution of zinc chloride and dyed with chay-root acquired a bright apple-green colour.

On calico prepared with oil and tannin matter and subsequently mordanted with alumina according to the ordinary Turkey-red process, Bancroft obtained colours very much like those given by madder. He discusses at length the

statements of various writers who, in describing the native processes make no mention of an alum mordant as being used or even thought necessary, but he conclusively demonstrates that the Hindus must have used it in some form or other, and suggests that its employment had escaped the attention of those who observed the native processes, either through ignorance of its importance or because the native dyers guarded it as a secret, or perchance it was present in the water employed.

Comparing European Turkey-red with that of Malabar, he considered that the former was quite equal to the latter in beauty and permanency, indeed the Indian red was usually not very bright, because soiled by certain brownish impurities, not removed by any clearing process as is usual in Europe, and hence it constantly improved in this respect by wearing and washing.

Gouffroy in his work entitled "L'art de la teinture des laines," speaks favourably of chay-root as a dyestuff and states that in 1834 a single firm in Elbeuf used 3,000 kilos. for wool dyeing, which shows that some firms at least appreciated its good qualities.

In 1832 M. Ed. Schwartz read a paper before the Industrial Society of Mulhouse giving the results of his experiments in conjunction with M. D. Keschlin on the dyeing properties of chay-root and a few other dyestuffs brought from India by Gouffroy. They refer to the fact that during a period of 15 years fruitless attempts had been made to introduce this dyestuff to Europe, both by the British East India Company and by various English and French merchants, and although Bancroft and other chemists who had examined the dyestuff had failed to obtain any very good results with it, they deemed it worthy of further experiment, especially in view of the extended knowledge then recently gained concerning madder and its colouring principles.

They found chay-root to have an acid reaction, and although this was less than in the case of "nona," *i.e.*, morinda root, they still found it desirable to wash the root with water before dyeing. They found it beneficial also to add ground chalk to the dye-bath to the extent of one-twelfth of the weight of the root. Turkey-red dyed with it stood the clearing process perfectly, and the colours produced on unmoiled calico were quite as brilliant and as fast to soap as those given by Avignon madder, to which dyestuff indeed it seemed to be very similar in its general dyeing properties. The only drawback to its adoption in Europe, according to these authors, was that it only contained one-fourth of the colouring matter present in a medium quality of madder. Nevertheless they considered chay-root to be more worthy of attention than other allied Indian dyestuffs because of its comparative freedom from a yellow acid principle, which being present in considerable quantity in the others would materially hinder their employment in Europe. They expressed the belief that by a more intelligent culture of these plants, and by leaving the chay-root for a longer period in the ground before gathering, the latter would no doubt become richer in colouring matter, and the others would probably have their properties beneficially modified. (Bulletin de la Société Industrielle de Mulhouse, V., pp. 302-306.)

Such is a brief résumé of all the published information concerning chay-root which we have been able to find. No examination of the chemical principles contained in the root seems to have been made by any chemist except M. P. Schützenberger, who in his *Traité des Matières colorantes* 2, 291 (1867), states briefly that he found it to contain alizarin and chlorogenin, and that it could readily be exhausted by a treatment with alcohol.

**Experimental Part.**—The results of our chemical examination of chay-root have already been published in the Journal of the Chemical Society (1893, p. 1160); we need therefore here merely remind you that the root contains chiefly ruberythric acid and but a very small amount of ready formed alizarin. The most interesting feature is that purpurin is entirely absent, and that there are present in small quantity several yellow crystalline substances not possessing the property of dyeing mordants, including two mono-methyl-ethers of alizarin, two dimethyl-ethers of anthragallol and

metahydroxy anthraquinone; other substances isolated were wax and rubicloric acid.

Although chay-root certainly contains acid principles which tend to dissolve off the mordants, we found no difficulty in dyeing with chay-root without submitting it to a preliminary washing process as recommended by Schwartz and Kœchlin. The only precautions necessary to be observed was to add 2 per cent. chalk to the dye bath, and to raise the temperature to the boiling point gradually, say in the course of  $1\frac{1}{2}$  hours, and to boil for  $\frac{1}{2}$ —1 hour. It presented therefore no features different to those met with in madder.

Comparative dyeing experiments on ordinary stripe-printed calico containing alumina and iron mordants, showed the dyeing power of chay-root to be equivalent to the presence of a percentage of 0.33—0.35 alizarin. Compared with ground madder-root of good quality it seemed to have about half its dyeing power when the comparison was made before soaping, but examined after soaping it was quite equal to madder. The reds, pinks, and chocolates had a distinctly bluer shade than those given by madder, and the lilacs were much fuller and brighter and very similar to those obtained from alizarin. This last feature alone ought to have secured a ready market for chay-root among the European dyers, previous to the introduction of artificial alizarin, and it seems to us somewhat strange that its marked suitability for lilacs should have escaped the observation of those who formerly made dyeing experiments with this root.

On oil-prepared calico mordanted with alumina, chay-root gave an excellent blue shade of Turkey-red, withstanding the operation of clearing with soap and stannous chloride better even than a madder dyed red, and quite equal to one obtained by means of artificial alizarin. Good brown, red, orange, and purple colours were also readily obtainable on wool and also on silk suitably mordanted with chromium, aluminium, tin, and iron, according to the ordinary methods usual with dyers. On wool, the colours not being submitted to any soaping operation, chay root seemed to possess about half the dyeing power of madder.

All the dyeing properties of chay-root are entirely consistent with the results of the chemical examination referred to, namely, the absence of purpurin or any other colouring matter except alizarin capable of dyeing mordanted cotton.

Boiled with dilute sulphuric acid chay-root yielded a garanceine of a very dark green colour and possessing about three times the dyeing power of the original root.

For our several supplies of chay-root we have to thank Dr. George Watt, Simla, Mr. W. Reid, Bombay, the late Mr. R. O. Campbell, London, and Messrs. Binny & Co., Madras.

#### *Rubia Sikkimensis.*

According to Dr. G. Watt, from whom the small sample examined was obtained in 1886, the roots of this plant furnish the brilliant red dye used by the hill tribes of the Naga Hills and Manipur, under the vernacular name of *mujam* (Manipur).

It is a stout handsome creeper found on the Eastern Himalaya, in Sikkim and Bhutan, in the Mishmi Mountains of Upper Assam, and in Manipur, and the Naga Hills.

*History.*—In the Calcutta Exhibition catalogue (1883), II., p. 55, Dr. Watt writes: "Apparently the Lepehas of Sikkim do not know that this plant yields the madder dye; but I suspect that the thick heavy roots which are sold in the bazaars, belong largely to this species, though probably used as an adulterant." Prior to 1874, the plant does not appear to have been named or even known to exist by botanists, it having escaped their attention or been mistaken for *R. cordifolia*.

Whatever similarity, however, there may be in the general similarity of the plants, the dried roots of the two species show a marked difference; those of *R. sikkimensis* are much thicker, rough and furrowed, and covered with a grey powdery pith-like substance, while those of *R. cordifolia* are round, smooth, and straight.

The method of dyeing cotton yarn red, with the roots of *R. Sikkimensis* as witnessed by Dr. Watt in Manipur was probably incomplete, in so far as no use of alum mordant

is mentioned, but enough is described to indicate that the cotton is probably prepared with oil and tannin matter, mordanted with alum and finally boiled with a decoction of the root, i.e., similar to the Turkey-red process.

The chemistry of ordinary *munjeet* or *munjit* (*R. cordifolia*) was studied by Stenhouse (Annalen, 130, 325; also Proc. Roy. Soc. 12, 633 and 13, 145), who showed that it contained essentially purpurin, along with an orange crystalline substance called munjistin, now known to be purpuroxanthin-carboxylic acid, as proved by Schunck and Reemer (Ber. 10, 172, 790).

*Experimental Part.*—A chemical examination of the *R. sikkimensis* root (Journ. Chem. Soc. 1893, 1157), showed that it contained essentially the same principles as munjeet, hence it may be considered that both owe their dyeing properties to the presence of purpurin, since munjistin does not dye mordants properly, and may therefore be regarded as the accompanying yellow substance peculiar to these roots, and which corresponds to those found in madder root.

The application of *R. sikkimensis* root in dyeing presents no difficulty whatever.

Calico printed with iron and alumina mordants may be dyed without any addition of calcium carbonate or acetate to the bath, since there is evidently a sufficiency naturally present in the root. Owing to the solubility of the colouring matter, the mordants quickly attract it even at a comparatively low temperature. Generally speaking the colours with the different mordants are similar to those obtained from madder, but the reds and chocolates are much bluer, being devoid of yellow, and the lilacs are decidedly greyer. The colours are, however, precisely similar to those obtained from *R. cordifolia*, the latter possessing merely a half more dyeing power. They do not bear the action of boiling soap solutions so well as the madder colours.

On oil-prepared calico mordanted with alumina a very bluish shade of red is given, much brightened by soaping but rendered very poor and dull if cleared with soap and stannous chloride. Chromium mordant on oil-prepared calico, gives also a much bluer toned chocolate colour than that given by madder, and with iron mordant a similar difference in the lilacs is apparent. On wool and silk mordanted with chromium, aluminium, tin, copper, and iron in the ordinary manner, colours similar to those obtained from madder are produced, the most marked difference being exhibited by the tin mordant with which *R. sikkimensis* gives a much brighter and yellower orange; in this respect however it does not differ from *R. cordifolia*.

Comparing the colours on ordinary stripe mordanted calico given by pure purpurin and by *R. sikkimensis*, a very marked difference is noticeable; the former gives very yellowish red and chocolate, full pinks and purplish lilacs, while the latter yields very bluish red and chocolates, bare pinks, and greyish lilacs. The poorness of the pinks points to the removal of mordant by some acid principle in the *R. sikkimensis*, but the striking difference in the tone of the reds we are at present unable to account for. Approximately we should say that the dyeing power of *R. sikkimensis* is equivalent to its containing 0.37—0.5 per cent. purpurin.

It may be added that a small sample of *R. khosia* also obtained from Dr. G. Watt during the Indian and Colonial Exhibition of 1886, yielded colours precisely similar to those given by *R. cordifolia* and *R. sikkimensis*, but it possessed a somewhat greater colouring power than either. No doubt, when we have an opportunity of examining it chemically, it will be found to contain the same colouring principles.

#### *Al, Ach, Saranji, or Morinda-root.*

This dyestuff is the root of *Morinda Citrifolia* (*Rubiacæ*), the so-called Indian mulberry, and the Togari wood of Madras. The genus was considered to be so nearly related to that of *Morus*, one species of which furnishes the yellow dyestuff Old Fustic, that its name was thereby suggested to Vaillant and composed from the words *Morus indica*. Numerous species are recognised, of which seven are indigenous to India, and some uncertainty prevails as to which of the species are employed for dyeing by the natives.

Some consider *Morinda tinctoria*, which is the chief dye-yielding species, to be but a wild form of *M. citrifolia*. The latter is a small tree or bush cultivated extensively in many parts of India, also in Burma and Ceylon.

The following are a few of the vernacular names by which it is known:—

Āl, aeh, &c. (Hindi); aeh, aieh, aebu (Bengali); surangi, hārtundi, &c. (Mar.); munja-pavattay, &c. (Tamil); nōna, maddi, &c. (Telugu). A common trade name is surangi or seringi.

No doubt the dye-stuffs Nona, Noona, Hachroul, and Atchroot mentioned by Gouffreville, Schwartz and Koechlin, and referred to in the works of Crookes, Calvert, and others, consist of the roots of this or some closely allied species. The plants are allowed to mature usually for about three years, although in some districts the time may be extended to four, five, or even ten years. If allowed to grow, the tree ultimately attains the height of 20 feet or even more, but after the first three or four years, when it is 2-8 feet high, the roots no longer yield the dye in any quantity. The mature roots which vary from three to four feet in length, and from  $\frac{1}{2}$  to 1 inch in thickness, are carefully dug up, dried in the sun, cut into short lengths and stored for sale. They have a yellowish-grey earthy appearance. A transverse section shows a yellow woody central portion of considerable toughness. The bark has a darker colour. Cold or hot water extracts merely yellow principles, but alkalis at once yield deep red coloured solutions.

Three qualities of the dyestuff, bearing different names, are distinguished, according as they are derived from the thick end, the middle part, or the thin end of the root. The thin roots are considered to be the best quality, the thicker ones being much inferior, and sometimes indeed almost useless. This difference is no doubt largely due to the fact that the colouring matter resides chiefly in the root-bark, of which there is necessarily a larger proportion in the thin roots.

The average commercial value varies from three seers of the thin, to ten seers of the thick quality per rupee (say  $1\frac{1}{2}$  d. to 4d. per pound).

In some parts of Bengal the bark is stripped from the stem of the plants, and the twigs also are used for dyeing, although they are much inferior to the roots; in Maimansingh even the juice of the leaves is used, but it only imparts to cotton a reddish-brown colour.

Frequently, as in Bengal, the cultivation is limited to meet local demands only, or it is grown, as in Orissa and in Burma, in the native gardens for home use. In the Nimar district in the central provinces, the cultivation is wholly in the hands of a caste called Aloes.

Sometimes it is allowed to grow as a weed in the weavers' homesteads to be used by them subsequently in their capacity also as dyers, or they depend entirely upon the wild plant found in sufficient quantity in the jungle.

Here and there however the roots collected in one part are largely exported to another part of India, as for example from the Central Provinces to Madras, from Malabar to Guzerat and Northern India, from Bakarganj in Bengal to the North-West Provinces and the Punjab, &c.

There is no doubt *Morinda*-root takes a foremost place among the fast red dyestuffs of India, and the Āl dye is said to be gradually supplanting the more expensive red obtained from chay-root, although it too is suffering from the introduction of European dyes in some districts.

Occasionally Āl root has been sent to Europe, but it seems never to have met with success in competition with madder. The Hindocs have probably used *Morinda*-root as a dyestuff from a remote period, and though there are no records of the early methods of dyeing employed, they were probably much the same as those now in use.

In Dr. G. Watt's Dictionary of the Economic Products of India, Dr. J. Murray has written, under the head of *Morinda*, a most complete account of the more important species, and full details of the native methods of dyeing are there given. Dr. McCann there reports that it is principally used for dyeing the thread or yarn out of which the coloured borders of the cotton garments worn by the lower classes are woven, and also for dyeing silk thread to

form the borders of the coarse silk fabrics known as *crench* or *enb* cloth. In many places it is used to dye pieces of a coarse cotton cloth known as *kunda* or *kharna*, or for thread to be afterwards woven into such cloth.

The colours given by Āl vary from a reddish yellow, through pink and various shades of red, up to dark brownish-red. The dye contained in the root bark seems to be the best red, whereas that contained in the woody part of the roots is more yellow than red.

The methods of dyeing vary very considerably in detail in different parts of India, but they are all similar in general principle, which may be briefly expressed by saying that they are all more or less crude processes of Turkey red dyeing as known in Europe.

The following process of preparing the cloth is said to be followed in Dinajpur:—"Cloth first cleaned and dried; then mix the ashes of plantain bark and leaves with a quantity of water sufficient to wet the cloth to be dyed; to this add castor-oil seed fried and pounded, mix well, and afterwards mix with this decoction mustard oil."

"Steep the cloth in this for one night; wash in the morning in this same decoction and dry. Repeat this process of steeping and washing the cloth in the same water, and drying, every day for fifteen days. Then wash the cloth in fresh water. On drying it is ready to receive the dye."

"The dyeing solution is prepared by cutting the roots or sometimes only the bark of the roots into small pieces, pounding them well or grinding them, and steeping or boiling in water. Generally the material to be dyed, prepared as above, is boiled with the roots in water, but sometimes after the roots have been treated as above, they are taken out and thrown away, and the cloth or thread is simply boiled in the water containing the dye extracted by the above process from the roots."

It is added that a great variety of substances are used as mordants or auxiliaries, among which one finds mentioned myrobalsam and alum. They are applied to the cloth after the cleaning (oiling) process, before the application of the dye, or in some cases either along with the oil, &c., or with the dyestuff; sometimes indeed the whole of the necessary ingredients are mixed together, and simultaneously applied to the cloth by a steeping or boiling process.

*History.*—About the year 1790 some of the powdered root under the name of *urtech* came into the hands of Dr. Bancroft, and he apparently found little or no difficulty in applying it both to wool and to cotton. On the former with alumina mordant he obtained a bright orange-red colour fast to light, and the action of the weather, and with a tin mordant, it yielded a bright and durable orange. On calico printed with alumina and iron mordants, separately or mixed, he obtained reds, purples, and chocolates, very similar to the analogous madder colours, and equally durable.

At that time he considered that it might be profitably imported into Europe, and that it possessed the advantage over chay-root, that it was less liable to deterioration during storage.

In 1832 Schwartz and Koechlin also examined this root, under the names Nona and Hachroul, and reported on its dyeing properties to the Industrial Society of Mulhouse, in the paper already alluded to under chay-root. They pointed out its extreme toughness as compared with madder and hence the greater difficulty experienced in grinding it. They referred also to the fact that of all the Indian rubiaceae examined by them, it contained the largest quantity of certain yellow principles of an acid character which not only necessitated the washing of the root with cold water before dyeing, but also made it requisite to add a certain proportion of carbonate of soda to the dye bath in order to have a perfectly neutral bath, and to the neglect of this precaution they ascribed the indifferent results obtained by others. They recommended that the root be dried at a low temperature, then ground as finely as possible, and washed with fifty times its weight of pure cold water, filtering the mixture, and pouring fresh water over the root collected upon the filter.

To the dye-bath they added one-fifth of the weight of the root of carbonate of soda, and having introduced the mordanted material, the temperature was raised gradually

to the boiling point. In this manner they were able to obtain on oil and alumina mordanted calico a very full red, which, on clearing in the usual manner with soap and stannous chloride, changed to a scarlet, resembling the Turkey-red obtained from madder. On ordinary calico printed with iron and alumina mordants, they obtained black, lilac, red, and chocolate, differing only from the analogous madder colours by having a much yellower tinge. All the colours stood soaping very well, still preserving their yellow tinge, the lilac alone being deficient in brilliancy.

Their conclusion was that since morinda-root only possessed one-third the dyeing power of a medium quality of madder, it could never compete with the latter in the European market.

At a later date, about the year 1848, some morinda-root was imported into Glasgow under the name of Soorancee with the intention of introducing it as a substitute for madder. It was submitted for trial to some of the most experienced and skilful calico-printers of the district, all of whom concurred in declaring it not to be a dye at all, and to be totally destitute of useful applications.

Professor Anderson of the Glasgow University hearing of this circumstance obtained a supply of the root, submitted it to a chemical examination, and succeeded in isolating from it a yellow crystalline product. Anderson found that this substance did not dye iron and alumina mordants printed and fixed on calico as usual with calico-printers, but cotton prepared with oil and mordanted with alumina as for Turkey-red assumed a dark brownish-red colour, devoid of beauty. The absence of dyeing properties in this *morindine* is readily explained, for we now know it to be a glucoside.

When submitted to dry distillation Anderson found morindine to yield an orange crystalline sublimate which he called *morindone*, and this same substance was also produced by boiling morindine with dilute mineral acids.

*Morindone* represents the true colouring matter of morinda-root, and accordingly Anderson found it to dye ordinary mordanted calico in the normal manner.

In 1852 Roehleider gave it as his opinion that morindine and morindone were identical with the ruberythric acid and alizarin derived from madder. That this was not the case was first adduced by Stein (J. Pr. Chem. 97, 234), and in 1887-88 Thorpe, in conjunction with Greenall and Smith (Jour. Chem. Soc. 52, 52 and 53, 171), showed conclusively the correctness of Stein's view, and further that the constitution of morindine corresponded to a *tri-hydroxy-methyl-anthraquinone*, alizarine being, as is well known, a *di-hydroxy-anthraquinone*.

The most recent experiments in dyeing with morinda-root made in this country are those of T. Wardle, a record of whose results are contained in his Report on the Dyes and Tans of India 1878-1887. No notes are given of the mordants and processes employed, and one cannot, therefore, follow his experiments, but he appears to have been unable to produce the Hindoo reds, and at most succeeded in producing from it yellow, orange, or brownish-red colours. In his concluding remarks he writes, "I was not successful in obtaining good red dyes from the samples labelled *morinda citrifolia* and *morinda tinctoria*. In each case I found a yellow colouring matter prevailed, and I was led to infer that good reds were not obtainable from these plants or their roots without admixture of the other red dyes such as mangit, &c.; but on visiting India I found undeniable evidence in Calcutta, the North-West Provinces, and Rajputana, and other parts of India of the constant employment of both these species yielding excellent reds on cotton, both in prints and dyes. The samples which had been sent to me I found were of very poor quality, and were too small for successful trials."

**Experimental Results.**—Having regard therefore to the extensive employment of morinda root as a red dyestuff by the natives of India, and the undoubted difficulties experienced by many European experts who have in the past attempted to apply it for the production of reds, our attention and interest was attracted to this dyestuff with the view of determining the best method of applying it successfully.

Further, although morinda-root has already been examined by several chemists and the nature of its chief colouring principle has been established, it seemed desirable to determine the character of those accompanying principles analogous to the yellow substances found in madder, chay-root, and munjeet, which from its botanical relationship it might naturally be expected to contain.

With respect to this part of our examination the results will be communicated at an early date to the Chemical Society, but it may already here be stated that several of the above mentioned yellow substances have been isolated in the crystalline condition. As to the essential colouring principle it is found to be present almost entirely in the form of the glucoside morindine which in the pure condition proves to be of a somewhat stable character.

Now it is well known that the colouring matter of the madder-root is there present also largely as the glucoside ruberythric acid, a substance devoid of dyeing properties with respect to mordants, although it will dye wool and silk a bright yellow colour. Moreover, it is a matter of common knowledge, thanks to the researches of Schunck, that the madder glucoside is split up under the influence of acids, alkalis, and ferments into glucose and the useful colouring matter alizarin.

In attempting, therefore, to solve the mystery connected with the successful application of morinda-root in dyeing, our first endeavours were directed to the splitting up of the glucoside of the root by one or other of the methods indicated as effectual in the case of madder.

Fermentation experiments were made with several weighed quantities of ground morinda-root. In one case, presuming some ferment might be naturally present in the root, 60 grms. of root were merely mixed with 700 cc. distilled water and left to stand for five days at a temperature of 35° C. A similar experiment was made with the addition of chalk sufficient to neutralise the natural acidity of the root. Other experiments similar to these were carried on simultaneously with the addition of a small percentage of ground madder-root, on account of its ferment; yeast was also tried. In all cases fermentation took place, and the mixtures were thrown on calico filters, drained and washed rapidly with four litres distilled water. The fermented roots were dried at a low temperature, and the loss of weight (14-17 per cent.) determined.

Eventually pieces of calico printed in stripes with alumina and iron mordants were dyed with equivalent amounts of the various fermented root and the root in its original condition. The latter scarcely dyed at all, whereas the fermented roots gave fairly good reds, chocolates, and lilacs similar to the analogous madder colours. The root fermented with yeast gave the best result. In all cases the addition of chalk to the fermenting mixture was injurious.

It was evident, therefore, that a considerable improvement in the dyeing power of the root had been effected, either by the fermentation or by the washing, but since better results were obtained by other methods carried on at the same time, the fermentation experiments were not continued.

To effect the decomposition of the glucoside by means of alkalis, barium hydrate was selected, for in the course of the purely chemical examination of the root it was found that not only could the glucoside morindine be split up by this agent, but the morindine produced, formed an insoluble lime compound, whereas the accompanying yellow substances formed soluble compounds. By boiling morinda-root, therefore, with lime-water and then washing, the whole of the yellow substances could be removed, and by a subsequent treatment of the residual root with acid and washing the calcium compound of the morindine could be decomposed and the lime removed, leaving behind a purified root containing only morindine in the free state.

For some reason or other the morinda root treated in the above-mentioned manner yielded only indifferent results in dyeing, and having regard to the number of operations required and the better results otherwise obtained in a simpler manner, the matter was not further inquired into.

Decomposition of the glucoside by acids resolved itself into the preparation of a garancine from morinda-root, and this was done not only with the root in its natural condition, but after it had been thrice washed for two hours with

madder, had the same dyeing power as  $1\frac{1}{2}$  lbs. of Nos. 5, 2, 4, and as 3 lbs. of Nos. 6 and 9. No. 8 was very poor indeed, and seemed to have been spoiled. All the above roots in their washed and dried condition had a more or less bright olive-yellow colour, except No. 8, which was decidedly brown.

The results of the foregoing experiments entirely corroborate those obtained by Schwartz and Koechlin, as to the necessity of washing the finely ground roots with water before dyeing, and the addition of an alkaline salt, chalk, or carbonate of soda, to the dye-bath in definite proportion, if good full rich reds, &c., are to be obtained. We never found it necessary, however, indeed it would have been injurious, to add to the dye-bath such a large proportion of sodium carbonate as 20 per cent. of the weight of the root. This difference is probably owing to the different method of washing adopted. Schwartz and Koechlin seem to have washed the root with a much larger quantity of water than we did, but for a short period only, indeed without any steeping at all apparently, whereas we steeped the ground root in three successive quantities of water for a total period of 25 or even 50 hours, and always with beneficial results. The comparatively slight solubility of the glucoside permits indeed of considerable washing of the root without entailing any material loss of colouring power, and it seems to us best to prolong the washing a little in order to escape the necessity of adding large per centages of chalk or sodium carbonate to the dye-bath; excessive washing however must of course be avoided, otherwise loss of dyeing power would ensue through loss of morindine.

One interesting feature in connection with morinda dyeing is, that although the washed root undoubtedly contains the colouring principle still in the form of the glucoside, and which is of marked stability, it nevertheless dyes extremely well. We are unable at present to explain this, and are inclined to think that the presence of the mordant on the fabric has some influence in the matter, although we have had no time as yet to study this point.

For our supply of morinda-root we have to express our thanks to Mr. W. Reid of Bombay, and to Sir F. A. Abel, Bart., of the Imperial Institute. Small samples were also obtained from Dr. G. Watt during his visit to England in 1885 in connection with the Indian and Colonial Exhibition.

#### *Mang-kudu or Wong-koudou.*

This dyestuff is the root-bark of *morinda umbellata*, and may be regarded therefore merely as a variety of the *Al* root of India.

Some of its Indian vernacular names are as follows:—*Al* (Bomb.); *nūna, kai, nūna marum* (Tamil); *mūlūghūdū* (Telugu); *mang-kudu* (Malay).

It is a shrub met with in the hilly regions of Eastern Bengal, also in South Western India, the Southern Konkan, the Nilgiri Hills, the mountains of Travancore, also in Ceylon, the Malay Peninsula and Java.

Although this dye-stuff, said to cost about 6d. per lb., is largely employed by the Javanese for producing the fast reds in their celebrated "*Baticks*," it does not seem to be specially used by the Hindoos, unless indeed the whole root is sold as *Al* root.

Some years ago we received a small specimen of mang-kudu, also "*Baticks*" from our friend Mr. F. Driessen of Leiden, on his return from Java, and to his firm *De Leidische Katoenmaatschappij* we are indebted for the 10 lbs. of root-bark with which our experiments have been made, and for the gift of which we here express our best thanks. Till recently, however, we were ignorant of its botanical origin and for definite information on this point we have to thank Mr. T. W. Thielton-Dyer, the Director of Kew Gardens, although we had already come to the conclusion that it must be some species of morinda root-bark owing to our recognition of its colouring matter as morindone.

The commercial dyestuff has the appearance of a somewhat reddish-brown and wrinkled bark, curled up into

irregular rolls. Water extracts from it only a yellow colour, but alkaline solutions are immediately coloured red.

*History.*—It does not appear to have been subjected to any extended examination either by dyers or chemists. Gonfreville refers to it in his "*L'art de la teinture des laines*," p. 489, as *jong-koutong* or *woon-koutou* coming from Java and associates it with *atch-root* which he had received from Bengal. He recognised its similarity to the root-bark of *nonna* (*Morinda citrifolia*), and although he gives it as the bark of a Chinese tree, he is inclined to think it is the root-bark of the same plant which yields *atch root*. On wool, silk, and cotton he was able to obtain with it by the aid of different mordants, orange, red, and especially fast dark colours. He considered it a very valuable dyestuff, and points out how highly esteemed it is by the Javanese. A large number of samples of cotton, linen, silk, and wool dyed with it were sent to the French Exhibition held in 1839.

Baneroff very briefly refers to morinda *umbellata* as being employed in Cochin China and other parts of Asia as a yellow dye, but does not seem to have had an opportunity of experimenting with it.

It was examined by Schwartz and Koechlin in 1832, under the name of *Ooungkoudou*, and its dyeing properties were reported upon in their communication to the Industrial Society of Mulhouse already referred to. They found it to possess only  $\frac{1}{2}$ — $\frac{1}{3}$  of the dyeing power of good Avignon madder, and although it contained a less proportion of acid yellow principles than munnjet, it nevertheless required an addition of 30 per cent. carbonate of soda to the dye-bath. The colours obtained from it were said to be neither so bright nor so fast as those derived from morinda-root (*nona*).

T. Wardle, in his *Monograph on the Dye-stuffs and Tanning Matters of India and their Native Uses*, descriptive of the Collection in the Indian Section of the Paris Exhibition, 1878, states that the roots of this plant yield a yellow dye, and with the addition of Sapan wood a red dye for cotton.

In Dr. G. Watt's *Dictionary of the Economic Products of India*, 1891, Dr. J. Murray reports that like all other members of this genus, the root yields a dye, but of a brilliant yellow, not a red, colour. From the small space devoted to it we imagine it must be a dye-stuff of little or no importance in India.

*Experimental Part.*—The chemical examination of this dye-stuff, now made for the first time, shows that it contains, like the root of morinda *citrifolia*, the glucoside morindone, also several other crystalline principles in small quantity, a full account of which will shortly be communicated to the Chemical Society of London.

Knowing the botanical origin of the dye-stuff and the colouring principle it contained, its application in dyeing presented no difficulty whatever. Certainly mang-kudu in its ordinary condition was not found useful in dyeing, but as in the case of *al* root, so here, a preliminary washing or steeping in water sufficed to remove the deleterious acid principles present, and thus to transform it into a valuable red dye-stuff. Here, too, an addition of 1.5 per cent. of sodium carbonate to the dye-bath was also found to be necessary.

Ordinary stripe-mordanted calico of the printer, as well as oil-prepared cotton mordanted with aluminium, chromium, and iron, all furnished excellent reds, purples, browns, and blacks, fast to soap, practically the same as the analogous colours produced from morinda-root, but much fuller since mang-kudu possesses a much greater colouring power than *al* root. This fact is, of course, not to be wondered at, for it is well known that in ordinary morinda-root the colouring principle is situated chiefly in the bark of the root.

Our results differ from those of Schwartz and Koechlin in so far, that they lead us to consider mang-kudu as a valuable dye-stuff for India, comparing very favourably indeed with madder. With respect to the yellow colour obtainable from it on silk and wool, referred to by T. Wardle and others, it is, of course, due to the glucoside morindone, and hence of questionable value as a permanent dye.

*Ventilago Madraspatana.*

The root-bark of this plant belonging to the Rhamnear and known in England as the "purple chuckway," furnishes a dyestuff much valued in Southern India.

Some of its vernacular names are as follows: pitti (Hindi); raktapita (Bengali); pappili chukka, saradattai, pupli (Tamil); popli-chukai (Kan).

It is an extensive climbing shrub, found in the Western Peninsula from the Konkan southwards, also in Ceylon and Burma.

At a certain period of the year immense numbers of coolies in Mysore proceed to the jungle to collect the root-bark, which is then conveyed to the nearest towns and sold to dealers, who export it to other districts of India.

The root-bark has the appearance of thin scales, ribbons, or filaments of a deep purplish or chocolate colour. When ground to powder, the dust which is given off irritates the throat in a marked manner. Boiling water or alcohol readily extract red caustic alkalis a deep crimson colour.

*History.*—Gouffreville refers to it as being employed in India and Java for dyeing silk, wool, and cotton fabrics either violet, brownish-red, or black, all of which are accounted permanent.

He gives a long list of the reactions of different chemical reagents upon a strong aqueous decoction, and seems to have made a few dyeing experiments with it himself, and by the use of tin, alum, and iron mordants obtained red, violet, and chocolate colours. In his day the price in different parts of India varied from  $\frac{1}{2}$ l. to 1l. per lb.

We find no reference to any other examination of this dyestuff having been made till 1878—1887, during which period samples of the root-bark were obtained by the India Office and submitted to Mr. T. Wardle. He found it to be exceedingly rich in a red colouring matter, capable of producing many colours, for which cochineal and madder are generally used, and well adapted for *tusar* silk. The colours obtained by him, but with what mordants he does not state, inclined towards purple and chocolate, but generally reds more or less pure. He had not the opportunity of testing them for fastness, but judged them to be fairly permanent. He believed it would be a valuable acquisition to the dye-house, and might be largely used if it could be obtained in quantity at the price of 3—5 annas ( $4\frac{1}{2}$ d.—7 $\frac{1}{2}$ d.) per lb., mentioned in a report by Surgeon-Major Bidie. Some writers state that in 1888—89 it was sold at as low a price at 1—1 $\frac{1}{2}$  annas ( $1\frac{1}{2}$ d.—2 $\frac{1}{2}$ d.) per lb. It seems to be collected annually to the extent of 1—3 tons.

No special chemical examination of the colouring matter seems to have been made hitherto; the only references on this point relate to the variously coloured precipitates given by aqueous decoctions with a few metallic salts, and are to be found in the *Pharmacographia Indiae* l. 355, of Dymock, Warden, and Hooper, where it is suggested that the colouring matter is probably one of the derivatives of anthracene, though on what grounds this statement is made is not given.

*Experimental Part.*—The results of our chemical examination of this dyestuff, which are not yet completed, will be submitted ere long to the Chemical Society of London; suffice it to say here that it contains a considerable quantity of a resinous colouring matter soluble in alcohol, and but slightly soluble in water, which is readily attracted by mordants.

On stripe printed calico the root-bark gives with alumina mordant a claret-red, much bluer than a limawood-red, and not unlike that of alizarin-bordeaux; with iron mordant a greyish lilac which in strong colours approaches a black; and with a mixture of the two a very purplish dark chocolate. The lilac differs entirely from that given by alizarin-bordeaux by being weaker and greyer, and is more similar to the one given by limawood. The colours are moderately fast to soap, very much better than limawood colours, but considerably behind the alizarin colours in this respect. In point of fastness of soap we should class this dyestuff with camwood, although the colours given by

ventilago with the different mordants differ materially in shade from those given by camwood, the reds being bluer, clearer or brighter, and less bronzy, and the lilacs weaker.

Comparative dyeing experiments made with the purified colouring matter showed that the root bark of ventilago contains 8—10 per cent colouring matter.

On oil prepared calico ventilago gives with alumina mordant a rich claret-brown, with chromium mordant a deeper purplish-brown or very black-purple, and with iron mordant quite a good purplish black.

On wool chromium mordant gives a good purplish-brown, alumina a bordeaux-red, tin a brighter red similar to an alizarin red with alumina mordant, and iron mordant gives dark dull purple and black. On silk similar colours are given.

No difficulty at all is experienced in dyeing with this dyestuff, the ordinary modes of mordanting suffice, and no additions to the dye-bath are necessary except in the case of wool, with which it is desirable to add calcium acetate in order to correct the strong acidity of the mordanted fibre. The chief noticeable feature perhaps is that, owing to the slight solubility of the colouring matter in water and its resinous character, the dyeing does not commence until the temperature reaches 70—80 °C.

The fastness of the colours to light have not yet been tested, but owing to the general similarity as we think of the dyeing properties of this dyestuff to those of limwood and camwood, we are not sanguine upon this point. Nevertheless, the strong colouring power of ventilago and the ease with which it dyes mordanted fabrics, coupled with its comparatively low price, warrants us in considering it a dyestuff worthy even of the attention of European dyers, and it certainly must be ranked among the ready useful dyestuffs of India.

For our supply of 10 lbs. of this dyestuff we express our thanks to Sir P. A. Abel, Bart., Director of the Imperial Institute, from whom and his coadjutors we have received every assistance in the supply of material.

Finally we may add that we have already been and still are engaged in examining the chemical and tinctorial properties of other Indian dyestuffs, *e.g.*, Kamela, *Tesla* flowers, &c., and hope in due time to submit to the Society a record of our experimental results.

## DISCUSSION.

Mr. G. W. SLATER regretted that the results of the earlier experimenters had been found to be incorrect; they might, perhaps, have worked with material differing in age and other particulars from that examined by the authors. As so many of the plants examined belonged to the order *Rubiaceae*, it would be worth while to examine whether all the members of this order do not yield dyestuffs.

Mr. RAWSON was glad that natural colouring matters were again being investigated. From the commercial point of view the most important question was, at what price could these dyestuffs be obtained. All the shades which they yielded could be produced equally well with alizarin, and, if these dyestuffs were to compete with this latter, the roots containing them would have to be produced at an exceedingly low price. Was the yellow dye on wool obtained with morinda root fast to light? And was the colouring matter obtained from ventilago fast?

Mr. WILKINSON said it was pleasant to him to find Gouffreville's work corroborated; it was work that had been a labour of love, as all who had read his work must recognise.

Mr. PERKIN said, in reply, that they had worked with larger quantities than the older experimenters used, and so were enabled to discover the presence of, and to remove, certain substances which had a deleterious effect upon the action of the dye; this was why they had obtained better results.

Prof. HEMMEL said that they proposed to extend the investigation to other members of the order *Rubiaceae* or allied plants. There was no probability that morinda

or chay-root would compete with artificial alizarin, for that had already displaced madder-root, which was at least as good as the two first named. They had rather, in their investigation, a desire to gain definite information regarding the chemical and technical properties of various Indian dyestuffs, many of which had not hitherto been examined. The yellow dye, obtained on silk or wool with mordant in an acid bath, was probably not fast to light; it had not, however, been tried in this respect. There was no absolute necessity to find a fast natural yellow, as several good artificial ones were known, *e.g.*, among the acid and benzidine dyes. He had heard, indirectly from a former director of a dyeing school in India, that a natural yellow very fast to light was known in that country. The colouring matter from *Ventilaga* was moderately fast to soaping. It was quite true that Gouffreville did work *con amore*.

The CHAIRMAN said that he felt sure the section was grateful to the authors for bringing forward the results of a piece of work fraught with many difficulties. Mr. Perkin, he believed, had one of the most treasured qualities of the organic chemist, the genius for crystallising, and had succeeded admirably in isolating the beautiful specimens which had been exhibited. It was worthy of note that the paper was the outcome of the assistance of two important institutions, the Clothworker's Company and the Imperial Institute. The functions of the latter body might seem to others as to himself somewhat indefinite, but there could be no doubt that a searching examination into the nature and value of Indian products was a matter of imperial importance. Whether or not these dyestuffs turned out to be specially useful, it was highly desirable that they should be investigated. Pictitious importance was apt to attach to materials coming from a distance, and it was possible that the treasured dyestuffs of the East might prove to be devoid of any of those special qualities of permanence and tint which were still erroneously supposed to differentiate natural from artificial colouring matters. The previous investigation of Indian dyestuffs appeared to have been imperfect and of limited practical value, and it was well that the Imperial Institute was taking up the matter again and securing an exhaustive examination both from the chemical and dyeing points of view.

## THE THEORY OF DYEING.

BY C. F. CROSS AND E. J. BEVAN.

In the last number of this Journal there appear two interesting communications upon this subject, both attacking what appears to be known as the "solid solution" theory, and substituting in general terms, presenting features of similarity, a counter-hypothesis basing the cause of dyeing phenomena primarily upon osmotic action, with the play of chemical reaction between the colouring matter and fibre substance as an auxiliary effect more or less operative. Both authors [Mr. Dreaper, p. 95, and Dr. Weber, p. 122] make mention of some observations of our own [*ibid.*, 12, 104], upon the theory in question, and upon a dyeing process of peculiar and significant bearing thereon, which we made in connection with researches on the chemistry of lignocelluloses. Mr. Dreaper has taken our interpretation of the phenomena as we intended it to be taken; Dr. Weber, on the other hand, has given an inverted and "improved" statement of our conclusions, which he will find in some measure corrected on reading Mr. Dreaper's paper, and which he will, no doubt, pardon our correcting further.

That the jute fibre when plunged into a solution of ferric ferrieyanide not only reduces the compound to the lower blue cyanides, but combines with the blue to the extent of 30—50 part of its weight, distributed with perfect uniformity throughout its substance and without prejudice to its lustre, is, it must be and is, in fact, admitted to be, unique in the range of dyeing phenomena. We were careful to insist upon the special chemistry of the reaction, and to point out that

it is by no means due to mere contact reduction by the aldehydic groups of the fibre substance, as suggested by Dr. Weber—the reaction proceeding in presence of powerful oxidants, such as chromic acid—but depends rather upon the special constitutional relationships of the reagents. We implied, in fact, that it must be interpreted as largely conditioned by the hexene configuration of the characteristic groups of the fibre substance in relation to the probable hexacentric formula of the ferric and ferroso-ferric cyanides; the "reduction" of the ferric ferrieyanide taking place within the fibre substance in virtue of a transference of oxygen, easily accounted for in the presence of CO groups of both Ketonic (R. Hexene groups) and Aldehydic (oxycellulose groups) function. [Ber. 26, 2520.]

We pointed out that the reaction might be considered as taking place in two stages: (1) the fixation of the ferric ferrieyanide by the fibre substance, and (2) the reduction or redistribution of oxygen, as above described, giving the well-known colouring matter. In evidence of the probability of (1), we showed that in the case of another colloid substance, *viz.*, gelatin, such a combination does take place, solutions of this colloid giving a pale greenish, opaque coagulum with the ferric ferrieyanide, converted by subsequent treatment with reducing agents into a transparent, deep blue jelly, which can only be regarded as a solution of the ferroso ferric cyanide (hydrate) in the "organic" colloid (or its hydrate).

From this statement it should be perfectly clear that we do not regard the entire reaction in the light of "a striking instance of solid solution." Dr. Weber, in crediting us with this view, does not sufficiently separate the *process* from the *product*. In the *process* it is quite obvious that the special chemical factors are predominant, and we emphasised it as further evidence of the special constitutional features of the lignocellulose. The *product*, on the other hand, is a solid solution of the pigment in the fibre substance; and we fail to see any necessity to resist the conclusion. The "improved" interpretation which Dr. Weber gives of the phenomenon or reaction, viewed as a whole, we will not criticise in detail. We notice, however, that his interpretation involves a contradiction in terms of his own conclusions, as to the mechanism of substantive dyeing in the case of cotton. In criticising us he says: "The location of the dye within the fibre is by no means a case of Witt's 'solution,' but merely proves the perfect intramolecular penetrability of the jute fibre by aqueous solutions. This perfect penetrability of jute fibre and all other fibres calls for no special explanation here, being an absolute condition of the growth and life of the vegetable and animal fibre." But when the author deals with cotton and the benzidine dyes, this particular fibre is found to have a one-sided penetrability; the process of direct dyeing with benzidine dyes is described "as an aqueous solution of a dye of very small co-efficient of diffusion formed inside the cellular cavities of the cotton fibre by means of a dye bath possessing a high osmotic pressure." We should like to know how the author would regard the dyeing of the jute fibre substance or structureless cotton cellulose with the benzidine dyes; or what function he would assign to the cellular cavities of cotton in direct dyeing with "primuline"?

This colouring matter in its relation to cotton is the subject of Mr. Dreaper's communication. This author also lays special stress upon the osmotic factors of the process of dyeing, and in our opinion does not fully recognise what is stated by the upholders of the "solid solution" theory, and also what is not stated, which under the present circumstances of the controversy is perhaps more important. In the primuline dyed *product*—and again we emphasise the distinction from the *process*—we have preëminent evidence of the existence of the colouring matter in solid solution.

The conception of solid solution we take to be an extension of the modern theory of solution to cover the case of homogeneous distribution of one solid throughout the mass of another, considered as the solvent. This modern theory, as we read it, is not so much an effort to account for the actual mechanism of solution, *i.e.*, the *process*, but concerns itself rather with the condition of the dissolved substance *in solution*. The consensus of evidence from the various

independent directions of investigation (Van't Hoff: Ber. 27, 6) leaves no doubt that it is a condition of dissociation or molecular simplification, such as has long been recognised to prevail in vapours and gases: that is that in a highly dilute solution of one substance in another (the solvent), the properties of the dissolved substance are those which it possesses when gaseified. In our opinion this conception perfectly explains the extraordinarily increased sensitiveness (to light) of diazotised primuline, when diazotised upon a fibre substance or other colloid basis (gelatin), as compared with its comparative stability as diazoprimuline *per se*. More than this: in our opinion there is no other explanation, in the present condition of our knowledge. No doubt in the case of primuline, as of the diazotised primuline, and a fully developed "ingrain" dye, there is a chemical bond of union with the fibre substance: but in virtue of that bond we should expect a decrease of molecular mobility, and therefore a decreased photo-sensitiveness of the diazo-product. To complete the evidence, however, we may remember that the synthesis of the primuline and fibre substance is of such an order that the capacities of the former for further synthesis remain perfectly unaffected; and that again is one of the essential features of *solution* as distinguished from combination.

To sum up these remarks we express our opinion that the dyeing of jute with ferroso-ferrie cyanide and cotton with primuline, are of unique and critical value in regard to the theory of solid solution as applied to the consideration of dyeing phenomena generally: that so far as Witt or others have given any exposition of such a "theory of dyeing," it has been in regard to the *dyed product*, as distinct from the mechanism of the actual process of transference of the dissolved dyestuff to the fibre substance. In elucidating the latter Dr. Weber's recent papers on "lake formation," and his later investigations of the function of the osmotic pressure of the dye solution, are of great interest and obvious value. The differentiation of this factor is only possible, with any precision, when applied to a series of bodies presenting definite constitutional variations. In this respect his choice of the benzidine series is well considered and his results will no doubt prove beyond criticism. But we would still ask him to recall the view of solid solution of the dyestuff in the colloid fibre substance, in spite of his attempt to dismiss it; and to separate this view from that of the *process*, in which we have a complicated play of chemical and physical effects.

In regard to the chemical effects involved they appear to be very largely of the order of double-salt formation. Dr. Weber himself has very largely contributed to our knowledge of the artificial colouring matters in regard to this as part of their activity: and investigation of the constitution of the substance of fibres of both animal and vegetable origin, continues to differentiate their reactive OH groups into those of acid and of basic function. In the case of crystalline double salts the bond of association is usually one of ascertained similitude whether in the function of the dominating element or the form of the individual salts. In colloid substances we have every reason to assume that coalescence is determined by likeness of configuration. What the nature of this "isomorphism" may prove to be in the relationship of *colloid* substances (usually described as "amorphous") is a problem which is being very distinctly opened out by the investigation of dyeing phenomena. In conclusion we take it that the theory of dyeing embraces the following factors:

1. The molecular constitution (configuration) of the reagents, colouring matters and fibre or tissue substance.
2. The presence of salt forming groups, chiefly OH groups differentiated in function both by the groups with which they are in immediate or proximate contact, as well as by the configuration of the C nucleus to which they are attached.
3. The condition of the colouring matter in solution measured by the physical constants of the solution and modified by the presence of the fibre substance in the dye bath.

The final result or dyed product may be considered *per se*, or in relation to the dyeing process: in regard to the

former we fail to see any objection to the theory of solid solution if indeed it is not a fact rather than a theory: as regards the process, which would therefore be a transference from one solution to another, the conditions of the transfer are both chemical and physical. Any theory embracing these conditions will no doubt assist in the advance of knowledge, but to exclude the consideration of the one or the other would be evidence that the subject had been approached from too narrow a point of view.

#### DISCUSSION.

Professor HEMMEL wondered if the jute fibre had been dyed by natural or by artificial light, since ferrieyanides, under certain conditions, were capable of reduction by light. Chromic acid, also, was sensitive to light and need not necessarily prevent the reduction of the ferrieyanide. He himself felt diffident in accepting Weber's view, that the colouring matter diffused through the cell wall into the interior of the cotton fibre, and was there deposited or dried on to the inner cell wall. If this was really the idea in Dr. Weber's mind, which he doubted, the authors put a pertinent question in asking Weber how he would explain, on this theory, the dyeing of amorphous cellulose. His own opinion had always been that the colouring-matter was uniformly distributed throughout the substance of the cell wall.

Dr. WEBER sent the following communication:—

What strikes me more particularly in this paper is the suggestion of the authors that in my paper (this Journal, 1894, 122) I gave an "inverted" account of the reaction between lignocellulose and ferrie ferrieyanide observed by them, and further that my statement of the "solution theory" of dyeing is not what Witt expounded. This announcement of Cross and Bevan I can only understand by assuming that they have not yet realised the difference between the "solid solution" theory, as pronounced by Van't Hoff and Arrhenius, and the "solution theory of dyeing" as put forward by Witt. Witt's "theory" is the outcome of the total misunderstanding of Van't Hoff's theory, which was originally meant to apply to metallic alloys and "isomorphous mixtures" only. Nobody in the least acquainted with the dyeing phenomena, on reading Witt's original paper, will doubt for a moment that Witt's theory does not profess to apply purely to the physical constitution of the dyed fibre as a whole, but distinctly assumes, in designed opposition to the chemical theory of dyeing, that the very process of dyeing, instead of being essentially the consequence of chemical differences between dyestuff and fibre, merely consists in the migration of the dye from one solvent into another. This is proved beyond doubt by the facts Witt cites in support of his theory, all of which are calculated to furnish evidence of the existence of the dye in the fibre in the free state. Witt is too experienced a dyer not to see that chemical interaction between dye and fibre once being granted, the "solid solution" theory becomes as superfluous as it would be for the explanation of the formation of barium sulphate from baryta and sulphuric acid. So much about Witt's notion of the function of "solid solution" in dyeing, which evidently has been as much misunderstood by Cross and Bevan as Witt misunderstood Van't Hoff. Cross and Bevan's complaint of my "inversion" of their experiment is evidently due to the same misunderstanding, as they seem to wish it to be taken as evidence of the state of the dyed lignocellulose, whereas my criticism was directed against the chemical mechanism or dyeing process underlying the reaction. But if the latter does not bear out or renders altogether superfluous their scantily supported hypothesis as to the final state of dye and fibre, a criticism of their experiment with regard to this point would have been superfluous.

Transference of a substance from one condition of solution to another is indeed, as Cross and Bevan assert, a solution phenomenon pure and simple. But then, no chemical change of the dissolved substance must be involved in passing from one solvent into the other. As I have, however, shown in my paper, such a chemical change is involved in all dyeing processes, with the single exception

of the dyeing of benzidine dyes on cotton. Consequently what Cross and Bevan maintain is dissolved in the fibre substance, is an altogether different compound from that held in solution in the dyebath. Cross and Bevan's contention that "the association of colloids in a dyed fibre is a case of double salt formation, the bond of union being probably an isomorphism of molecular configuration," I cannot argue; the meaning of this sentence is as obscure to me as the writings of Paracelsus.

With regard to the considerable difference between the sensitiveness to light of diazopyrimuline produced upon the fibre and of the same compound in the free state respectively, this is certainly a point of considerable interest, but Cross and Bevan have adduced no evidence warranting their bold assertion that this is due to the dye on the fibre being in "a condition of molecular simplification or disaggregation." The authors are greatly mistaken in saying that this is all the solution theory asserts, and I repeat that Witt's theory is not a theory of the state of the dyed fibre alone, but also of the process of dyeing. If Cross and Bevan object to this interpretation, they will have to come forward with a solution theory of their own. They may, however, find some difficulty in this task, for a theory regarding the state of the dyed fibre, but unavailable for the elucidation of the dyeing process, contains all the elements of a scientific abortion.

The three points to be borne in mind, according to Cross and Bevan, in the working out of a theory of dyeing, have been very fully considered in my paper, which, indeed, gives a full account of the chemical mechanism of the phenomena in question. Their finding that this is not so, I can only take as proof that they have not sufficiently digested the contents of my paper.

By a curious coincidence a paper on the theory of dyeing was read before the London Section of our Society by Mr. Dreaper on the same evening as that on which I brought my paper before you. The result of Mr. Dreaper's valuable investigations, in which he attacked the question from quite a different point than I did, leads essentially to the same result as my own, *viz.*, to an unconditional rejection of the solution theory as propounded by Witt.

## ON THE MORDANTING OF WOOL WITH CHROMIUM.

### PART IV.

BY L. LICHTI AND J. J. HUMMEL.

(See also this Journal, 1893, 240 and 332; 1894, 222.)

THE following communication is a continuation of our study of the behaviour of chrome alum as a mordant for wool when it is employed along with acids as assistants. In our previous communication (this Journal, 1894, 222) we cited the effects produced by the addition of sulphuric acid and acetic acid, we propose now to refer to the action of oxalic, tartaric, and chromic acids, and then briefly to the behaviour of one or two other chromium salts as mordants for wool.

#### 3. Chrome Alum and Oxalic Acid.

At a very early period dyers must have noticed that when wool is mordanted with alum alone poor colours are obtained in dyeing, and in order to avoid this defect they began to add, along with it, organic acid, in the form of cream of tartar. No doubt its employment in preference to other acids was the result of pure empiricism, and who the discoverer was is altogether unknown. At the present time one endeavours, wherever possible, to economise by replacing it with the much cheaper oxalic acid.

In the course of the following experiments it was noticed that when organic acids were employed along with chrome alum for mordanting wool, the green solutions became more and more violet according to the amount employed, from which it would appear that their addition retards or prevents dissociation of the chrome alum. Comparing the effect of equivalent amounts of oxalic and tartaric acids the latter gives greener solutions, and such as show less

tendency to become turbid. Closely connected with this is the fact that an addition of oxalic acid to a chrome alum solution only partially prevents its precipitation by caustic soda, whereas an addition of tartaric acid entirely prevents it. Altogether the behaviour of these two acids towards chrome alum is somewhat different.

In determining the efficacy of oxalic acid as an assistant along with chrome alum the first question which arises is, ought it to be used in the free state, or half or wholly neutralised with soda. The results vary somewhat according to the amount of oxalic acid employed. With 2 mols. oxalic acid per 1 mol. chrome alum the best results were obtained with the free acid, with 3 mols. it was best to have the acid half neutralised.

*Experiment 24.*—Wool was mordanted with—

- (1.) 10 per cent. chrome alum + 2 mols.  $\text{H}_2\text{C}_2\text{O}_4$  (oxalic acid).
- (2.) 10 per cent. chrome alum + 2 mols.  $\text{NaHC}_2\text{O}_4$ .
- (3.) 10 per cent. chrome alum + 2 mols.  $\text{Na}_2\text{C}_2\text{O}_4$ .

No. 3 bath gave one the impression of being alkaline, its colour being yellowish green, and it showed distinct evidences of dissociation by its turbidity at the end of the operation, whereas No. 1 bath was perfectly clear, No. 2 bath showing an intermediate appearance. No. 1 felt seemed to be the best mordanted, then Nos. 2 and 3. The colour of the dried mordanted wool was a pale greyish green, No. 3 being distinctly yellower and paler than the others. The patterns were dyed with 40 per cent. quercitron bark; No. 3 was much paler than No. 1, indeed scarcely half as deep, and it exhibited differences in colour in the different fibres, to which reference has previously been made, in a more marked manner than in Nos. 1 and 2.

The result of this experiment is that neutral mordants are distinctly unfavourable for wool.

When the experiment was repeated with 3 mols. oxalic acid instead of 2, the 3 mols.  $\text{NaHC}_2\text{O}_4$  seemed to act slightly better than 3 mols. of the free acid, no doubt because this is already an excess of acid.

*Experiment 25.*—Six fents of wool were mordanted with the following:—

- (1.) 10 per cent. chrome alum.
- (2.) 10 per cent. chrome alum + 1 cc. normal oxalic acid ( $= \frac{1}{2}$  mol.).
- (3.) 10 per cent. chrome alum + 2 cc. normal oxalic acid ( $= 1$  mol.).
- (4.) 10 per cent. chrome alum + 3 cc. normal oxalic acid ( $= 1\frac{1}{2}$  mols.).
- (5.) 10 per cent. chrome alum + 4 cc. normal oxalic acid ( $= 2$  mols.).
- (6.) 10 per cent. chrome alum + 5 cc. normal oxalic acid ( $= 2\frac{1}{2}$  mols.).

With increasing amounts of acid the dissociation apparent in No. 1 liquor gradually diminishes, No. 3 is still faintly turbid, Nos. 4, 5, and 6 are quite clear.

The dried mordanted fents appear as follows:—No. 1 yellowish green, No. 2 similar to No. 1 but less yellow, Nos. 3 and 4 are still less yellow, No. 5 has the deepest colour, a greyish green, No. 6 is slightly paler than No. 5. It is interesting to note that in gas light the mordanted fents exhibit a peculiar reddish tint, and one is tempted to entertain the opinion that the chromium is present on the fibre in some peculiar soluble condition. The liquors too, with increase of oxalic acid, acquire a reddish tint, which may possibly be explained by supposing that a part of the chromium has been taken up by the fibre as  $\text{Cr}_2(\text{SO}_4)_3$  in addition to free sulphuric acid, and that in the bath there remains  $\text{Cr}_2(\text{C}_2\text{O}_4)_3$  as well as  $\text{Cr}_2(\text{SO}_4)_3$ . This change of colour occurs only during the mordanting process, notwithstanding the presence of the oxalic acid the hot liquor is first green, but while the wool gradually acquires a greyish-green colour the bath becomes more and more violet, appearing when cold distinctly red, quite like the colour of pure chromium oxalate. On heating chrome alum solution with 3 mols.  $\text{Na}_2\text{C}_2\text{O}_4$  without presence of wool, a violet solution is also obtained, showing therefore that interaction occurs at least partially; here the sulphuric acid would be taken up by the NaOH in place of the wool.

If the above-mentioned opinion is correct, the purpose of the necessary additions of cream of tartar, tartaric acid, oxalic acid, &c., is evidently to prevent the decomposition of the alum through the absorption of the sulphuric acid by the wool.

The six fests of the present experiment were dyed with 12 per cent. alizarin, with the result that No. 5, i.e., the mordant  $\text{Cr}_2(\text{SO}_4)_3 + 2\text{H}_2\text{C}_2\text{O}_4$  gave the best colour. Under the microscope No. 1 showed dull red and almost colourless fibres, differences which became less apparent from Nos. 2 to 4, and almost disappeared in Nos. 5 and 6. It may be added that a much deeper claret colour was obtained if the wool mordanted with chrome alum and 2 mols. oxalic acid and washed was passed, previous to dyeing, through a very dilute sodium carbonate solution; for 600 cc. water 0.53 grms.  $\text{Na}_2\text{CO}_3$ , i.e.  $(\frac{1}{1000000})$  mols.).

A further observation may be here cited. The appearance of the waste dye-liquor of No. 5 indicated that it contained excess of alizarin, and possibly chromium mordant as well, and this proved indeed to be the case, since on boiling in it a small piece of wool (1.66 grm.) it acquired a pink colour. Wool mordanted with chrome alum and 2 mols. tartaric acid exhausted the dye-bath somewhat more, and the waste dye-liquor dyed a piece of fresh wool a paler pink than the foregoing in consequence. Altogether, wool mordanted with the addition of tartaric acid seemed to be better mordanted, the yellowish-green line being replaced by one of a pure greyish green.

**Experiment 26.**—In this experiment the intention was to discover, if possible, the conditions necessary to prevent the different behaviour of individual wool fibres, since this hinders materially the utility of chromic oxide salts as mordants.

- (1.) 10 grms. wool were first boiled for an hour in 600 cc. water, and then mordanted with 10 per cent. chrome alum, and 2 mols. oxalic acid.
- (2.) 10 grms. wool were boiled for an hour in 600 cc. water with addition of 4 cc. normal oxalic acid (2 mols.), then 1 grm. (1 mol.) chrome alum was added, and the boiling continued for  $1\frac{1}{2}$  hours longer.
- (3.) 10 grms. wool were mordanted in the ordinary manner with 1 grm. chrome alum, and 4 cc. normal oxalic acid (2 mols.).

All the liquors acquired a violet colour, the mordanted wool having a greyish-yellow-green colour, No. 2 being deeper than No. 3. When dyed in alizarin, No. 1 gave the deepest and best colour; then came No. 2, and finally No. 3. Since No. 1 is better than No. 2 the action seems to be physical rather than chemical, as though the preliminary boiling of the wool softened the fibre, and caused it to absorb the mordant better.

**Experiment 27.**—The object of this experiment was to determine the behaviour of pure chromium oxalate as a mordant. The preparation of this salt was effected as follows: a cold and very dilute solution of chrome alum was precipitated with the calculated amount of  $\text{NaOH}$ , and the precipitate after frequent washing with water was collected on a filter, and ultimately dissolved in the calculated amount of oxalic acid.

Wool was mordanted with the following:—

- (1.) 10 per cent. chrome alum + 3 mols. oxalic acid.
- (2.) 10 per cent. chrome alum + 6 mols.  $\text{NaOH}$ , the precipitate being at once dissolved by adding 3 mols.  $\text{H}_2\text{C}_2\text{O}_4$ .
- (3.) 10 per cent. chrome alum + 3 mols.  $\text{Na}_2\text{C}_2\text{O}_4$ .
- (4.) An equivalent amount of pure chromium oxalate prepared as stated above.
- (5.) As 4, but with addition of  $\frac{1}{2}$  mol.  $\text{H}_2\text{SO}_4$  (i.e. 1 cc. normal acid) in order to neutralise the water and the wool.

The liquor of No. 4 was perfectly clear, of a violet-green colour, and mordanted the wool very well, giving it a full greenish-violet-grey colour; No. 5 behaved similarly; Nos. 2 and 3 gave results a little below those of No. 4; the wool mordanted with No. 1 had the palest colour, and this liquor seemed to be decidedly acid.

When dyed in alizarin Nos. 4 and 5 appeared the best colours, Nos. 2 and 3 were less bright, and No. 1 was distinctly the palest. Here, as in all cases where alizarin was used as the dye-stuff, calcium acetate was added to the dye-bath in an amount sufficient to form calcium alizarate.

Chromium oxalate gave much better results than chrome alum and 2 mols. oxalic acid, or than chromium fluoride, and since this mordant is comparatively cheap it may be strongly recommended for use on the large scale. To correct the temporary hardness of the water employed a little sulphuric acid would require to be added to the bath.

A microscopic examination of the dyed fibres supported this favourable view, and it may be added that of all the chromium oxide salt mordant baths that of chromium oxalate was the best exhausted, and the dye-bath following it, in the case of alizarin, was almost entirely exhausted. Here, too, a little chromium oxalate bled out into the dye-bath, as was shown by the waste dye-liquor being capable of dyeing a piece of fresh unmordanted wool. This fact was indeed not to be wondered at, since the 10 per cent. chrome alum employed was far too large an amount, and would, if it had been all fixed on the wool, have taken up 36 per cent. of alizarin (20 per cent. paste). For a nice claret-red, however, 12 per cent. alizarin is sufficient, and this requires only  $\frac{1}{3} = 3.33$  per cent. chrome alum.

It is certainly interesting to find that approximately this very amount of mordant is fixed by the wool, both when bichromate of potash and when chrome alum and oxalic acid (2 mol.) are employed.\*

This agreement, with respect to the amount of chromium fixed, to which reference was already made in Part II., notwithstanding the great difference in the chromium salts employed, seems to favour the view that a chemical combination exists between wool, chromium, and colouring matter.

The study of mordants and their action is one of extreme difficulty, and we are still far from understanding all the questions involved, hence the desirability of this branch of study being pursued more than it is at present. It would be important to discover, if possible, mordanting processes in which the baths are exhausted, so that the dyer who wishes to work according to strict chemical principles is able to fix, on successive quantities of goods, exactly the same amount of mordant. Suppose, for example, one has to mordant equally, 100 woollen pieces with bichromate of potash, in 10 lots, 10 pieces in each lot. According to some of the methods at present adopted, especially that one in which the bath is freshened up with additional mordant before entering the next lot of goods, an equal mordanting of the several lots of pieces is quite impossible. In the case of dyeing dark shades, the foreman dyer, by means of trial bits and frequent matching, will succeed with more or less success to obtain the shade required.

If, however, the problem is to dye a pale shade with alizarin, alizarin-blue, or coerulein, dyes which cannot be boiled off or on at will, inequalities in the different lots are scarcely to be avoided. In this case one is compelled to dye them according to a definite receipt. If now the work-chemist could introduce some volumetric analytical methods to determine rapidly the condition, acidity, &c. of the mordant baths, and if he determined previously the amounts of colouring matter required, it would then be possible to work with greater certainty of obtaining a good result. The peace of mind which would thus come to the dyer by knowing that the two essential elements were right, would leave him free to devote all his attention to other necessary but subsidiary points to ensure complete success. In this manner the period of suspense, the uncertain successive additions of dye-stuff, and the necessarily more lengthened boiling, would all disappear, and a larger output of finer goods would be the result. Another advantage in dyeing,

\* See this Journal, 1893, p. 243, concluding paragraph of second column, where, however, the passage should read thus: "Taking the view that only on third of the bichromate is really effective, and that for a full claret colour that is required 12 per cent. alizarin (20 per cent. paste), we find that the proportions are just those which are requisite to form normal chromium alizarate."

according to a definite receipt, would be that the shades would be obtained almost as well by artificial as by day light.

When wool is mordanted with organic chromium salts it never acquires quite the same green colour as that of chromic hydrate; the peculiar violet-greenish-grey colour always gives one the impression that a chromium salt is present in the fibre. Although wool absorbs organic as well as mineral acids, a dissociation of the chromium oxalate bath could never be detected; on the other hand, this occurred when in one experiment wool was mordanted in the basic chromium oxalate  $\text{Cr}_2(\text{OH})_2(\text{C}_2\text{O}_4)_2$ ; in this case, in which there was a deficiency of acid, the wool acquired a fine green colour.

At this point a few preliminary experiments will be referred to, in which wool was mordanted by padding in mordant solutions, then drying and steaming. The solutions were of such concentration that the amount of mordant presented to 10 grms. wool was equivalent to 1 gm. chrome alum.

(1.) Chromium oxalate applied in this manner gave a tint which, after washing, had a fine full greyish-green level colour. On dyeing with logwood a specially fine black was obtained; differences in the colour of individual fibres were small.

(2.) Chromium oxalate, with 1 mol. oxalic acid, gave a greyish-brown-green coloured wool, not quite level; the dyed colour was fairly good.

(3.) Chromium oxalate with 2 mols. oxalic acid gave a fine greyish green colour with violet tint; the dyed colour was not so good as the previous one; evidently there was already too much acid present.

(4.) Chrome alum gave an uneven yellowish-green pale chromic oxide colour; the dyed colour was worse than when oxalic acid was employed.

(5.) Chromium chloride and (6) chromium nitrate gave very poor results, worse even than the following:—

(7.) Chromium acetate gave an uneven yellowish-green colour; the dyed colour was very bad. The microscope revealed the greatest differences in colour in the different fibres, although chromium acetate is not dissociated, a fact which shows clearly that wool can only be properly mordanted with chromic salts in acid solution. In the case of chrome alum alone the differences in colour of individual fibres were very great, indeed even in the different parts of the same fibre, but by the addition of oxalic acid these differences became less marked; no colourless fibres were seen, at most such as were greyish-blue and bluish-black.

(8.) Chromium fluoride gave an uneven yellowish-green colour; the dyed colour was somewhat better than that given by chrome alum; blue as well as black fibres were noticed under the microscope.

One point worth noting in connection with wool mordanted in the ordinary manner is, that the less acid the mordanted wool is, the lower the temperature at which it begins to dye. Wool mordanted with chromium oxalate was strongly acid, and began to dye with alizarin only at a temperature of 70° C. As soon, however, as the calculated amount of calcium acetate was added to the bath, the wool began at once to acquire a deep colour and the bath was soon entirely exhausted, although it still had an acid reaction at the end of the dyeing process, having previously passed through a neutral if not even a slightly alkaline condition. It is here plainly evident that the acid previously absorbed by the wool is slowly bleeding out into the dye-bath.

Already in 1886 Liechi and Schwitser showed that wool mordanted with  $\text{Al}_2(\text{SO}_4)_3$ , when boiled several times with distilled water gave acid liquors, and that in the case of aluminium tartrate and oxalate the dye-baths were all acid; further, it was shown that no better colours were obtained by boiling out the mordanted patterns with water previous to dyeing (see Mittheilungen des techn. Gewerbe Mus. Wien, III., p. 48, &c.)

In order to throw if possible more light upon this question, the following experiments were made.

*Experiment 28.*—Wool was boiled with 10 per cent. chrome alum and 2 mols. oxalic acid. The fent was dried

and divided, one half being washed in a cold alkaline solution containing 10 grms.  $\text{NaHCO}_3$  per litre; both patterns were then dyed separately with alizarin and calcium acetate. The neutralised wool exhausted the dye-bath better, and acquired a deeper colour. Under the microscope, however, it did not seem as if really more colouring matter had been fixed, but rather that the increased depth was due to the alkaline condition of the colour.

*Experiment 29.*—In all the waste alizarin dye-liquors examined showing an acid reaction, although calculated amounts of calcium acetate were employed, one could always detect excess of lime and alizarin. It seemed probable, therefore, that the acidity of the bath prevented to some extent the entrance of the calcium into the colour-lake in the fibre, and that it might also be the cause of the well-known bleeding of alizarin colours during the milling process. This idea suggested the following experiment:—

First of all it was accurately determined how much lime water corresponded to 1.2 grms. alizarin (20 per cent. paste), with the result that to form the compound  $\text{C}_{14}\text{H}_8\text{CaO}_4$ , 42 cc. were found to be necessary. Woollen fents were then mordanted in the following baths:—

- (1.) 10 per cent. chrome alum and 2 mols. oxalic acid.
- (2.) 10 per cent. chrome alum and 2 mols. tartaric acid.
- (3.) Equivalent amounts of chromium oxalate.
- (4, 5, 6.) 10 per cent. chrome alum and 2 mols. oxalic acid.
- (7, 8, 9.) Same as No. 3.

During the mordanting process a slight difference in the colour of the various baths was noticeable, the oxalic acid baths being more violet, the tartaric acid baths more greenish violet, while the mordanted fents of the former were of a greyish-yellow green, and those of the latter greyish violet.

The fents Nos. 1—3 were dyed with the above-mentioned solution of  $\text{C}_{14}\text{H}_8\text{CaO}_4$ . Up to a temperature of 60—70° C. the wool acquired very little colour, so that it seemed necessary to neutralise the excess of lime with acetic acid. Of the theoretical amount of acetic acid required,  $\frac{1}{2}$ — $\frac{1}{4}$  sufficed for neutralisation. This dyeing experiment with  $\text{C}_{14}\text{H}_8\text{CaO}_4$  led to the conclusion that the acid chromium compound absorbed by the wool corresponds to the formula  $\text{Cr}_2\text{O}_3 \cdot 5 \text{ acid}$ . The chromium oxalate mordant bath was most exhausted, and the corresponding dye-bath was almost completely exhausted, a fine, full, deep claret colour being obtained. The claret obtained on the chrome alum and tartaric acid mordant was somewhat bluer in shade than that with chrome alum and oxalic acid, and both were somewhat paler colours than that on chromium oxalate mordant.

The best mordanting action is undoubtedly obtained when the chromic oxide is combined with an organic acid such as oxalic or tartaric acid.

The fents Nos. 4, 5, 6 were well squeezed after mordanting, and then dyed with 30 per cent. logwood, No. 4 being dyed without any further treatment, while No. 5 was first heated for a quarter of an hour with 600 cc. water containing 0.8 per cent. sodium acetate, and No. 6 with water containing 0.3 per cent. chalk; after thus neutralising the acidity of the wool, the logwood was added, and the dyeing proceeded with. The waste dye-liquors of Nos. 4 and 5 were decidedly acid; No. 6 was neutral. The amounts of these additions were proportional to the amounts of acid absorbed by the wool, as found previously; bath No. 5 was, of course, not really neutralised, but contained acetic acid equivalent to the oxalic or sulphuric acid absorbed. The dyed pattern No. 4 was a somewhat deep, fine, blue-black; No. 5 was slightly darker; No. 6 was bronzy, evidently through want of acid.

Incidentally, patterns Nos. 4, 5, and 6 showed plainly, what is invariably the case, that chromic oxide mordant with logwood does not give a real black. If one uses pure crystalline haematein, the colour obtained is a very fine dark blue, hence it is that some chemists consider that true chrome black is not a compound of chromic oxide with haematein, but with some oxidation product of haematein, and that a good black is only to be obtained with the use of chromic acid mordants. This fact is well known to practical wool dyers. Calico-printers, too, have long been in the habit of printing a mixture of logwood liquor (haematoxylin) and

chromic oxide salt, and then submitting the steamed fabric to a supplementary oxidation, or oxidising agents have been already added to the printing mixture.

Patterns Nos. 7, 8, 9, after mordanting, were well squeezed, and then dyed with 10 per cent. alizarin, No. 7 being dyed without any further addition. No. 8, with addition of 35 cc. lime-water, neutralised exactly with acetic acid, and No. 9 with 35 cc. lime-water only.

The waste dye-liquor of No. 7 was acid, and contained free alizarin; in addition of NaOH it gave a fair quantity of chromium-alizarin lake, which showed, therefore, that in the absence of lime a good deal of chromium oxalate had out into the dye-bath. The dye liquor of No. 9 was only neutral at the very end of the operation, and was perfectly exhausted. No. 8 was very similar. Both gave mere traces of alizarin-lake in addition of caustic soda. The intensity of colour increased from Nos. 7 to 9, No. 9 being a deep bluish claret-red, while No. 7 was much paler and redder. All three patterns were satisfactorily level, even when the fibres were examined under the microscope. Very probably the colours of patterns Nos. 8 and 9 would stand milling better than if dyed on chrome alum and oxalic acid or cream of tartar. Under the microscope No. 4 showed the palest colour with logwood, and the fibres showed slight differences in colour, evidently because of the different amounts of acid absorbed; the colour was a fine blue, not quite so dark as No. 5, which still showed irregularity. No. 6 was still better, a fine dark blue of normal appearance, with fibres of fairly equal colour. Through an error of calculation, too much  $\text{CaC}_2\text{O}_4$  had been used; probably with the right amount the result would have been still better. Of course, in practice, the amount to be used would vary according to the quality of the water employed; hence it is unnecessary to give further details on this point.

In the case of alizarin, No. 9 pattern showed the effect of an alkaline bath, but here it is very necessary to avoid all excess of calcium carbonate, otherwise loss of alizarin may readily occur.

#### *Chemistry of the action of Oxalic Acid as an assistant.*

It has long been recognised in practice that ordinary alum when used alone is unsuitable for mordanting wool, and in an empirical manner it was found that the addition of cream of tartar gave better colours, which would not rub off so readily. The idea appears to have been that it acted beneficially by reason of its solvent action, a view which seems to be both natural and rational in the light of our results concerning the decomposition of chrome alum by the wool, from which we have seen that an addition of acids or acid salts (e.g., cream of tartar) really prevents the precipitation of insoluble basic sulphate, and the consequent rubbing off, &c. Hummel and Gardner have already shown that comparatively large amounts indeed of tartar are necessary to obtain good results, and that a much smaller proportion of oxalic acid is not only as good but even better than cream of tartar in the case of chrome alum. Experiments by Liechti and Schwitzer have also tended to show the utility of oxalic acid as an assistant in mordanting wool, and its comparatively low price is also favourable. When, however, the attempt is made to study its action more closely by analytical methods, difficulties are at once encountered.

It has been already shown that with increasing amounts of oxalic acid (and the same holds good with tartaric acid), that with the use of 2 mols. oxalic acid to 1 mol. chrome alum dissociation is prevented, and that larger amounts give less favourable results on dyeing. Further it will have been noticed that with the increase of acid used, the differences in colour in the different fibres becomes less and less, that the greatest evenness of colour can be obtained by using the chromic salts of organic acids, and the general appearance and beauty of the dyed colour is thereby improved. Dyeing experiments with azo colours have shown that individual wool fibres differ greatly in their absorbent power for acid.

To throw some light on the subject the most suitable method seemed to be to analyse the spent mordant liquors, and the following experiments are attempts in this direction. In some cases the amount of acid absorbed by

the wool was determined volumetrically; in others we endeavoured to determine the relative amounts of chromic oxide, oxalic acid, and sulphuric acid which must be present in the wool after the mordanting operation. To determine the quantity of these three substances remaining on the wool after washing seemed practically impossible and was not attempted. Sufficiently exact results have unfortunately not been obtained, but it seems evident that a relatively larger proportion of acid than of chromic oxide disappears from the bath, which leads us to the conclusion that the mordanting substance fixed on the wool must be of an acid character rather than a hydrate or basic salt as usually stated in the text-books and technical journals. The titration of a chrome solution containing oxalic acid and the estimation of the chromium itself are very uncertain; oxalic acid as well as alkali seem to be dragged down with the precipitate, so that frequently one may observe on calcining the presence of chromate of soda as well as chromic oxide, and by re-dissolving, reduction, and re-precipitation the loss of a little substance is scarcely to be avoided. It was frequently observed, too, that the oxalic acid dissolved the ferric oxide present in the wool as an impurity, and this of course would contaminate the chromic oxide. Considering these things, and remembering the action of the ammonia given off by the wool, we are far from relying upon the formula given subsequently as representing the true nature of the compound fixed upon the mordanted wool. It may suffice, however, for the present to make the following statements: that when organic acids are used as assistants, no decomposition of the chrome alum occurs, that much less chromium (e.g. 40 per cent.) is fixed than when chrome alum alone is used, and indeed as an acid compound.

*Experiment 30.*—Three fents of wool were mordanted as follows, with—

(a.) 10 per cent. chrome alum and 2 mols. oxalic acid (equiv. to 0.4 grms.  $\text{SO}_3$ ). The spent liquor was titrated with normal NaOH, and showed an absorption of acid equivalent to 0.2744 grm.  $\text{SO}_3$ , i.e., = 0.33614  $\text{H}_2\text{SO}_4$ . This number agrees well with the 0.3332 grm. absorbed by wool when boiled with water containing 10 cc. normal  $\text{H}_2\text{SO}_4$ .

(b.) 10 per cent. chrome alum and 1.5 mols. oxalic acid. The amounts of acid absorbed by the wool in two experiments were:

(1.) 0.2716 gr.  $\text{SO}_3$  = 0.33371 gr.  $\text{H}_2\text{SO}_4$   
(2.) 0.2688 „ „ = 0.32928 „ „

(c.) 10 per cent. chrome alum and 3 mols. sodium oxalate.

The bath contained:  $\text{Cr}_2\text{O}_3$  : 0.10692 grm.  
 $\text{SO}_3$  : 0.20129 „

The wool therefore contained:  
 $\text{Cr}_2\text{O}_3$  : 0.04608 grm.  
 $\text{SO}_3$  : 0.03871 „

which corresponds to a substance having the following composition:  $\text{Cr}_2\text{O}_3$  : 1.6  $\text{SO}_3$ .

A complete decomposition had not taken place, no doubt because of the need for acid by the wool. In this case, of course, the presence of the  $\text{Na}_2\text{O}$  prevents a large amount of the  $\text{SO}_3$  from being absorbed by the wool, and therefore it remains in the bath.

We have seen above that from chrome alum 0.159 grm.  $\text{SO}_3$  is absorbed by the wool, while here only 0.03871 grm.  $\text{SO}_3$  is taken up, i.e., about one-fourth. In its place, however, oxalic acid has been absorbed, which dissolves the basic sulphate and hence corresponding better results are obtained. We have, namely—

	Chrome Alum alone.	Chrome Alum + 3 mols. $\text{Na}_2\text{C}_2\text{O}_4$ .
In the bath.	14.3 per cent. of the $\text{Cr}_2\text{O}_3$ .	69.8 per cent.
„ wool.	85.7 „ „	30.12 „
„ bath.	33.75 „ of the $\text{SO}_3$ .	87.80 „
„ wool.	66.25 „ „	12.20 „

Calculated for equivalent amounts of  $\text{Cr}_2\text{O}_3$ , the wool absorbs in the case of chrome alum 66.25 per cent. of the  $\text{SO}_3$ , while for chrome alum and sodium oxalate only 34.7 per cent. According to the result of titration, acid equivalent to 0.18972 grm.  $\text{SO}_3$  must have been absorbed; if one subtracts from this 0.3871 grm., there remains the equivalent of 0.14801 grm.  $\text{SO}_3$ , which is equal to 0.233116 grm. oxalic acid. This, combined with the 0.94608 grm.  $\text{Cr}_2\text{O}_3$ , would correspond to the compound:

That the wool has undoubtedly absorbed an acid compound may also be deduced as follows:—The quantity of  $\text{Cr}_2\text{O}_3$  remaining in the bath requires as a salt an amount of acid corresponding to 4.19 cc. normal  $\text{NaOH}$ ; since, however, only 1.332 cc. were used in titration, the bath must, therefore, have contained essentially a basic chromic oxalate, consequently an acid chromium salt must have been fixed upon the wool. Further, the short series of experiments made in connection with the dyeing of series of shades, from dark to pale, show conclusively the truth of the view that acid mordants must be employed. Moreover, the very existence and character of the "single-bath" process for wool has long indicated that the theory of the fixing of the metallic mordants as hydrates or basic salts is untenable. In this connection preliminary experiments have shown that as the amount of mordant is decreased the amount of acid to be used therewith must be proportionately increased, and we might regard a single-bath process as one in which there is a rapid succession of mordanting and dyeing operations recurring in the same bath.

The fact that organic acids are here preferable to mineral acids is probably connected with the chemical constitution of the wool fibre itself. It is interesting that acetic acid, although it prevents the dissociation of the chrome alum, is absolutely worthless as an assistant.

(d.) 10 per cent. chrome alum and 2 mols. oxalic acid.

The bath was found to contain:  $\text{Cr}_2\text{O}_3 : 2.035 \text{ SO}_3 : 0.23 \text{ oxalic acid.}$

The wool was calculated to contain:  $\text{Cr}_2\text{O}_3 : 5.175 \text{ SO}_3 : 6.09 \text{ oxalic oxide.}$

Although in this case the oxalic acid was only calculated and not determined as such, still it is at least certain that in the bath there is relatively too little and in the wool too much  $\text{SO}_3$  in combination with the  $\text{Cr}_2\text{O}_3$ , which points again to an acid compound being on the wool.

(e.) In this experiment an attempt was made to determine the oxalic acid as such, and the following numbers were obtained:—

The total amount of acid absorbed by the wool, in terms of  $\text{SO}_3$ , was according to titration 0.2744 grm. On the wool there was found to be 0.0785 grm.  $\text{Cr}_2\text{O}_3$ , from which it is calculated, expressing the oxalic acid in terms of  $\text{SO}_3$ , that the wool contained the compound  $\text{Cr}_2\text{O}_3 : 6.68 \text{ SO}_3$ .

By gravimetric analysis the bath was found to contain 0.0745 grm.  $\text{Cr}_2\text{O}_3 + 0.08446 \text{ grm. SO}_3 + 0.09513 \text{ grm. oxalic acid}$ ; this amount of oxalic acid is equivalent to 0.6604 grm.  $\text{SO}_3$ , therefore together, the amount is 0.14486 grm.  $\text{SO}_3$ , from which one may calculate that the bath contains the equivalent of  $\text{Cr}_2\text{O}_3 : 3.72 \text{ SO}_3$ .

The wool then contains: 0.0785 grm.  $\text{Cr}_2\text{O}_3 + 6.1556 \text{ grm. SO}_3 + 0.15687 \text{ grm. oxalic acid}$ , the latter being equivalent to 0.6996 grm.  $\text{SO}_3$ , therefore, together the amount is 0.2551 grm.  $\text{SO}_3$ , from which one may calculate that the wool contains the equivalent of  $\text{Cr}_2\text{O}_3 : 6.215 \text{ SO}_3$ . Now by volumetric analysis the acid found was equivalent to 6.68  $\text{SO}_3$ , which is sufficiently concordant, having regard to the difficulties connected with the determination.

Considering the oxalic acid as such, there would, according to the foregoing calculation, be present on the wool the compound:  $\text{Cr}_2\text{O}_3 : 3.78 \text{ SO}_3 : 2.42 \text{ oxalic acid}$ , that is, as previously found, an acid compound; while in the bath the compound would be  $\text{Cr}_2\text{O}_3 : 2.167 \text{ SO}_3 : 1.55 \text{ oxalic acid}$  (= 3.715 acid groups).

In this case 51.3 per cent. of the chromium presented to the fibre was actually fixed on the fibre. The oxalic acid

was determined by permanganate of potash. Not feeling certain about the results given under (d), the analysis given under (e) were repeated.

(f.) 10 per cent. chrome alum and 2 mols. oxalic acid.

In this experiment the spent liquor contained 0.0991 grm.  $\text{Cr}_2\text{O}_3 + 0.1116 \text{ grm. SO}_3 + 0.084 \text{ grm. oxalic acid}$ , i.e., per  $\text{Cr}_2\text{O}_3$  = 3.174 acid groups, or  $\text{Cr}_2\text{O}_3 : 2.154 \text{ SO}_3 : 1.020 \text{ oxalic acid.}$

The wool contained 0.0539 grm.  $\text{Cr}_2\text{O}_3 + 0.1284 \text{ grm. SO}_3 + 0.168 \text{ grm. oxalic acid}$ , i.e., per  $\text{Cr}_2\text{O}_3$  = 8.33 acid groups, or  $\text{Cr}_2\text{O}_3 : 4.55 \text{ SO}_3 : 3.78 \text{ oxalic acid}$ , which is a more acid compound than was found in experiment (e). Here, of the chromium presented to the fibre, only 35.2 per cent. was fixed on the wool. The experiments (e) and (f) differ in so far that in (e) 1 cc. normal  $\text{HCl}$  was added to the bath to neutralise the alkalinity of the wool and the water. In (f) 2.43 cc. normal  $\text{NaOH}$  were required to neutralise the spent liquor, and since the amount of oxalic acid left in it corresponds to 1.33 cc. normal  $\text{NaOH}$ , if this is subtracted there remains 1.1 cc., as having been used in this case for neutralising water and wool.

If instead of free oxalic acid its sodium salt is used as assistant, a compound containing less  $\text{SO}_3$  will be fixed on the wool; 3 mols.  $\text{Na}_2\text{C}_2\text{O}_4 + 1 \text{ mol. oxalic acid}$  along with chrome alum would probably give good results, if one does not wish to employ chromium oxalate, which represents the best mordant.

#### 4. Chrome Alum and Tartaric Acid.

In the first instance a comparison was made of the efficacy of free tartaric acid, cream of tartar, and sodium tartrate, as assistants, with the result, as in the case of oxalic acid, that it is best to use free tartaric acid. This being so it may at once be recommended to practical dyers that, after making an analysis of their cream of tartar, they should add to it the requisite amount of sulphuric acid to liberate the tartaric acid, and for the sake of convenience keep a standard solution of the mixture ready for use.

Experiment 31.—Samples of wool were mordanted as usual with:—

- (1.) 10 per cent. chrome alum + 2 mols. tartaric acid (= 3 per cent.).
- (2.) 10 per cent. chrome alum + 2 mols. cream of tartar (= 3.76 per cent.).
- (3.) 10 per cent. chrome alum + 2 mols. sodium tartrate (= 4.2 per cent.).
- (4.) 10 per cent. chrome alum + 3 mols. tartaric acid.
- (5.) 10 per cent. chrome alum + 3 mols. cream of tartar.
- (6.) 10 per cent. chrome alum + 1 mol. tartaric acid.

Here again it was noticed that the neutral bath was of a yellowish-green colour, the acid baths more and more bluish-green with increase of acidity, indicating that the less acid and neutral baths had a tendency to precipitate a basic chromium salt, while the more acid baths retained the chromium in more stable solution, a fact also indicated by the faint reddish tint of the wool. Even with 3 mols. tartar mordanted wool, when dry, appears grey-yellowish-green, whereas with 3 mols. cream of tartar it has a decided pink-greyish-green colour. The tartar mordanted wool also appears paler than the corresponding tartaric acid mordanted felt, while the one with which sodium tartrate was used is paler still. When the patterns are examined by gas light, as in the case of oxalic acid, those from the more acid solutions have a more pronounced reddish appearance than those from neutral solutions, e.g., neutral chromium oxalate gave a pale heliotrope-grey tint, and only with a certain amount of free acid did the wool appear of a reddish hue; pure chromium tartrate mordanted wool too had only a faint reddish tint. This reddish tint appears more pronounced with oxalic acid than with an equivalent amount of tartaric acid. Already in the experiments previously referred to it was noticed that wool mordanted with  $\text{K}_2\text{Cr}_2\text{O}_7 + 2 \text{ mols. cream of tartar}$  appeared only very slightly of a pink tint, whereas when mordanted with  $\text{K}_2\text{Cr}_2\text{O}_7 + \text{H}_2\text{SO}_4 + 2 \text{ mols. cream of tartar}$  the pink tint became more pronounced. The more the chromium mordanted wool has a yellowish-green hue the worse the results on dyeing and the

more do they approach the "*couleurs alcalins*" of Havrez; with increasing amounts of acid the wool becomes more greyish-green to violet grey-green. It is impossible to fix definitely the best amount of acid to employ, since this depends on the absolute quantity of chrome salt and especially on the amount of water employed. With 10 per cent. chrome alum, for example, 2 mols. tartaric acid were found to be sufficient, with smaller amounts 3 mols. gave better results, but this point will be referred to again later on. Mordanting with 6.75 per cent. chrome alum and tartar, and using 1,000 cc. water, logwood gave a colour of only half the intensity of that given when 600 cc. water were used. Interesting as this fact in itself may be, it renders most difficult, if not impossible, the attainment of positive results in this class of research work. It gives rise also to practical difficulties to overcome which requires the close observation and attention to details. Suppose for example a dyer after much experimenting has devised a very good receipt for a particular mordant, say, for 50 kilos. wool and a corresponding amount of water. If, now, in a subsequent operation only 20-25 kilos. wool are mordanted in the same vessel, *i.e.*, with the same amount of water, and the amounts of mordant and acid are proportionately reduced, he will frequently obtain different results. In this case the remedy would be to use a little more acid, to which no doubt many a practical dyer has been led by careful and intelligent observation even though he has possessed little or no chemical knowledge. Practice is not infrequently in advance of theory, and this has often been the case in connection with dyeing; it is probable that with a little more readiness on the part of dyers in communicating observations regarding defects, or the improvements met with in the course of their daily work, would facilitate the progress of the science connected with dyeing.

The above five woollen fents were dyed in alizarin with the result that the best results were obtained with 2 mols. tartaric acid; 2 mols. cream of tartar gave a slightly paler and less even colour. If, however, 3 mols. cream of tartar (No. 5) are used, the colour is very good, and it is somewhat remarkable that with cream of tartar we may use tolerably large amounts without seriously affecting the colour, *e.g.*, even 6 mols. seem to be still favourable, whereas in the case of tartaric acid, 2 mols. are distinctly better than 3 mols., although if only 5 per cent. of chrome alum is used, 3 are better than 2 mols. Comparing tartaric acid and oxalic acid, 2 mols. of the former give a finer and bluer shade of Bordeaux than 2 mols. of the latter.

An examination of the mordanted material under the microscope gave the following result: slight differences of colour in the different fibres were noticeable in No. 1, but they were less than in No. 6 and 2; little difference existed between Nos. 4 and 5; No. 3 was the worst.

On putting a little unmordanted wool into the waste dye-liquor of No. 1, it acquired a pale pink colour (single bath), which was much paler than was obtained in the analogous experiment with oxalic acid, moreover the mordant bath was most exhausted; neutral and basic baths were always less exhausted.

The amount of acid absorbed by the wool from No. 2 mordant bath expressed in terms of  $\text{SO}_3$  amounted to 0.2744 grms. It may also be added that the less acid the mordant bath is the lower the temperature at which the dyeing of the fibre begins.

**Experiment 32.**—Samples of wool were mordanted as follows, and subsequently dyed with alizarin.

- (1.) Mordant as usual with 10 per cent. of chrome alum + 2 mols. tartaric acid (= 3 per cent.).
- (2.) Boil with 3 per cent. of tartaric acid, then add 10 per cent. chrome and continue boiling.
- (3.) Mordant with chromium tartrate, equivalent to 10 per cent. chrome alum.

The finest and darkest Bordeaux colour was given by No. 3; No. 2 was distinctly better than No. 1, but the difference between the two was less than in the analogous experiment with chrome alum and oxalic acid.

If samples of wool were padded with the following equivalent solutions, then dried and steamed—

- (a.) Chrome alum + 1 mol. tartaric acid.
- (b.) " " + 2 " "
- (c.) " " + 2 mol. cream of tartar.
- (d.) " " + 1 " "

(a.) acquired a greenish violet-grey colour; (b.) a similar tint, although there were evidences of the wool being already too acid; (c.) was also similar to (a.) with a distinct violet tint; (d.) was paler than (b.). When dyed in logwood, unsatisfactory grey shades were obtained, of less value even than the corresponding colours obtained with oxalic acid.

**Experiment 33.**—Wool was mordanted as follows:—

- (1.) 10 per cent. chrome alum + 3 mols. tartaric acid.
- (2.) 10 per cent. chrome alum was precipitated with 6 mols.  $\text{NaOH}$ , and the precipitate redissolved by adding 3 mols. tartaric acid.
- (3.) 10 per cent. chrome alum + 3 mols. sodium tartrate.
- (4.) Chromium tartrate equivalent to 10 per cent. chrome alum.

The appearance of the waste mordant liquors was as follows: No. 1, violet-blue-green; Nos. 2 and 3, slightly turbid and less exhausted; No. 4, clear, violet-green.

The colour of the mordanted wool decreased in intensity in the order 4, 1, 3, 2; No. 4 being a fine dark green, No. 1 a violet-grey. When dyed in alizarin No. 1 gave the finest and darkest colour, bluer in shade than with chromium oxalate, and the dye-bath was well exhausted. No. 1, although apparently well mordanted, gave the palest colour, no doubt because the mordant was already too acid; Nos. 2 and 3 were dark colours, but not very bright, probably the mordants were in these cases not sufficiently acid; No. 2 was somewhat better than No. 3. We have already seen that when using a mixture of chrome alum and sodium oxalate the inter-action under the conditions imposed is not complete. No. 2 is of course really a chromium tartrate prepared in the mordant bath, and ought certainly to give good results if a little more tartaric acid is employed.

**Experiment 34.**—Wool was mordanted with the following:—

- (1.) Chromium tartrate, equivalent to 10 per cent. chrome alum.
- (2.) As No. 1, with addition of 0.272 grm. sodium acetate.
- (3.) As No. 1, with addition of 0.098 grm. sulphuric acid.
- (4.) As No. 1, with addition of 0.150 grm. tartaric acid.
- (5.) Chromium oxalate, equivalent to 10 per cent. chrome alum.

The appearance of the spent mordant liquors was as follows: No. 1, clear, violet-green; No. 2, dark green with violet tint, less exhausted than 1; No. 3, clear, violet-green, not darker than 1; No. 4, similar to 3, or somewhat paler; No. 5, greenish-violet.

The mordanted wool appeared as follows: No. 1, a fine dark green; No. 2, paler green than 1; No. 3, a green paler and greyer than 1; No. 4, the darkest green; No. 5, a greenish-violet-grey.

When dyed with 12 per cent. alizarin (20 per cent. paste) the colours were as follows: No. 1, a fine full Bordeaux; No. 2, about half as deep a colour as 1; No. 3, the depth of colour was between that of 1 and 2, and the hue somewhat redder; No. 4, a better colour than 3, but somewhat paler than 1, and about equal to 5; No. 5, a fine colour, but still not quite equal to 1.

The result of this experiment was to show that the best of all chromic oxide salts as a mordant hitherto examined is chromium tartrate; chromium oxalate is almost as good, and to be preferred in practice because cheaper. The object of using sodium acetate in No. 2 trial was that it might act as a weak alkali perchance the compound  $\text{Cr}_2\text{O}_3 \cdot 3 \text{C}_2\text{H}_3\text{O}_2$  might be too acid, but as noted, the result was very poor.

When dyed with quercitron bark the chromium oxalate mordant gave a full greenish-yellow colour; if the amount of acid was reduced the greenish hue gave place to one more yellowish. A peculiar dark greenish colour was given with chromium tartrate + 3 mols. hydrochloric acid.

The difference in action between chromium sulphate and chromium tartrate is truly remarkable, for whereas the former is almost entirely decomposed, and scarcely mordants the wool at all, the latter mordants it in the best possible manner.

So far as our present knowledge of the wool fibre goes, it seems to us that the cause of this difference lies, first, in the greater affinity of the wool for sulphuric acid, and secondly, that the organic acids are capable of forming much more basic and at the same time soluble compounds than is the case with sulphuric acid.

*Experiment 35.*—This and the following two experiments were made with the view of determining the conditions necessary to obtain a graded series of level shades in a rational manner. Woollen patterns were mordanted in the ordinary manner as follows:—

- (1.) With 20 cc. chromium tartrate, equivalent to 1 gram. chrome alum.
- (2.) With 10 cc. chromium tartrate, equivalent to  $\frac{1}{2}$  gram. chrome alum.
- (3.) With 5 cc. chromium tartrate, equivalent to  $\frac{1}{4}$  gram. chrome alum.
- (4.) With 2.5 cc. chromium tartrate, equivalent to  $\frac{1}{8}$  gram. chrome alum.

The liquors of Nos. 3 and 4, even during the mordanting process, exhibited an alkaline character; No. 4 was pale green and slightly turbid; No. 3 was similar but darker in colour; No. 2 and 1 were clear and violet-green. A drop of methyl-orange solution coloured No. 1 crange-red; No. 2, reddish orange; No. 3, orange; and No. 4, yellowish-orange.

The mordanted fents appeared as follows:—

No. 1, a fine dark green; No. 2, pale green; No. 3 and 4 were yellowish cream colour, and appeared to be deficient in acid.

The fents were dyed with an excess of alizarin in order to saturate the mordants, the amounts chosen, viz., 18, 9, 4.5, and 2.25 per cent., corresponding to half the chromium being fixed on the fibre. Nos. 1 and 2 were deep claret reds, but Nos. 3 and 4 were dull bluish-toned colours which appeared as if the mordant had not been sufficiently acid, and reminded one of the "couleurs alcalins" of Havrez.

Before proceeding farther it seemed desirable to repeat this experiment, but with the modification of adding to each mordant bath 1 cc. normal tartaric acid in order to neutralise the alkalinity of the wool and the water.

*Experiment 36.*—Woollen fents were mordanted as follows:—

- (1.) With 20 cc. chromium tartrate, equivalent to 1 gram. chrome alum.
- (2.) With 10 cc. chromium tartrate, equivalent to  $\frac{1}{2}$  gram. chrome alum.
- (3.) With 5 cc. chromium tartrate, equivalent to  $\frac{1}{4}$  gram. chrome alum.
- (4.) With 2.5 cc. chromium tartrate, equivalent to  $\frac{1}{8}$  gram. chrome alum.
- (5.) With 1.25 cc. chromium tartrate, equivalent to  $\frac{1}{16}$  gram. chrome alum.
- (6.) With 0.625 cc. chromium tartrate, equivalent to  $\frac{1}{32}$  gram. chrome alum.

each with the addition of 1 cc. normal tartaric acid.

The spent mordant liquors of Nos. 1, 2, 3 had an acid reaction, No. 4 was almost neutral, and Nos. 5 and 6 quite so. After dyeing with proportional amounts of alizarin, the waste dye-liquors tested as follows:—No. 1 acid, No. 2 slightly acid, No. 3 very slightly acid, Nos. 4—6 neutral.

The dyed colours were somewhat better than the series in the last experiment, but it was evidently necessary to determine by experiment the amount of acid to be added for each amount of mordant, in order to obtain the best colour. Although the experiments are incomplete and the amounts of acid found necessary only hold good for the

conditions here imposed, and must vary somewhat in practice according to the character of the wool and the water employed, the following details are given to show the method adopted.

*Experiment 37.*—Several fents of wool were mordanted as follows:—

- (1.) With 10 cc. chromium tartrate, equivalent to 0.5 gram. chrome alum.
- (2.) With 10 cc. chromium tartrate + 1 cc. normal tartaric acid.
- (3.) With 10 cc. chromium tartrate. + 2 cc. normal tartaric acid.
- (4.) With 10 cc. chromium tartrate + 3 cc. normal tartaric acid.
- (5.) With 5 cc. chromium tartrate, equivalent to 0.25 gram. chrome alum.
- (6.) With 5 cc. chromium tartrate + 1.5 cc. normal tartaric acid.
- (7.) With 5 cc. chromium tartrate + 3 cc. normal tartaric acid.
- (8.) With 5 cc. chromium tartrate + 4.5 cc. normal tartaric acid.
- (9.) With 2.5 cc. chromium tartrate, equivalent to 0.125 gram. chrome alum.
- (10.) With 2.5 cc. chromium tartrate + 1.05 cc. normal tartaric acid.
- (11.) With 2.5 cc. chromium tartrate + 2.10 cc. normal tartaric acid.
- (12.) With 2.5 cc. chromium tartrate + 3.15 cc. normal tartaric acid.
- (13.) With 2.5 cc. chromium tartrate + 4.20 cc. normal tartaric acid.
- (14.) With 2.5 cc. chromium tartrate + 5.25 cc. normal tartaric acid.

Baths Nos. 4, 8, and 14 each contain as much tartaric acid as is contained in 20 cc. chromium tartrate alone, in the others the amount is conveniently reduced.

The waste mordant liquors tested as follows:—No. 1 slightly alkaline, 2—4 gradually more acid, No. 5 decidedly alkaline, 6—8 clear and apparently exhausted, Nos. 9 and 10 alkaline, 11 and 12 less so, 13 and 14 acid.

The appearance of the mordanted wool was as follows:—Nos. 1—4 green, gradually increasing in depth, No. 5 yellowish, No. 6 similar but more greenish, Nos. 7—8 all a fine green, No. 9 decided yellowish tint, Nos. 9—14 more and more greenish in tint.

When dyed in alizarin Nos. 1 and 2 had an appearance as if alkaline, No. 3 seemed to have had the right amount of acid, although No. 4 was still a good colour, No. 5 was pale and evidently an alkaline colour (Havrez). No. 6 was much better, No. 8 was already worse than No. 7, so that the best amount of acid seemed to be between Nos. 6 and 7, No. 9 was a very poor alkaline colour, No. 10 was little better, Nos. 11 and 12 were slightly better, No. 13 seemed to be of the normal colour, while No. 14 appeared to have been too acid. It may be added that an addition of acetic acid to the dye-bath appeared to act somewhat injuriously if the right amount of acid was present in the mordant bath, the colours being rendered thereby paler.

From this experiment it seems certain that if the dyer desires to work in a strictly rational manner, he must use for decreasing amounts of colouring matter proportionately smaller amounts of mordant, and at the same time add to the mordant bath, with respect to the  $R_2O_3$ , gradually increasing amounts of the assistant acid in order to obtain full bright level colours. The details no doubt require to be worked out in each individual case. In the experiment cited and the conditions observed, the best proportions of acid to use are—

- For 10 per cent. chrome alum about ( $Cr_2O_3$  : 3 mols.  $C_4H_4O_6$ ).
- For 5 per cent. chrome alum about ( $Cr_2O_3$  : 5 mols.  $C_4H_4O_6$ ).
- For 2.5 per cent. chrome alum about ( $Cr_2O_3$  : 8 mols.  $C_4H_4O_6$ ).
- For 1.25 per cent. chrome alum about ( $Cr_2O_3$  : 10 mols.  $C_4H_4O_6$ ).

An exact determination is difficult, because according to the amount of acid present the shade is bluish or reddish, and this variation prevents one from accurately estimating the comparative intensity of colour. To complete the study of this point it would be necessary to determine quantitatively the amount of chromium fixed on the wool in each bath, and from this to calculate the corresponding amount of alizarin to be employed. For a total fixation of 10 per cent. chrome alum one would require to use 36 per cent. alizarin (20 per cent. paste). The 10 per cent. alizarin usually employed in these experiments corresponds fairly well to the amount of chromium fixed in the mordant bath.

From the foregoing result it is evident that the custom in practical receipts of expressing additions of acid to the bath in percentages of the weight of wool used is perfectly justified. In the case before us the condition of the mordant bath to be observed approaches that of constant acidity, and reminds one forcibly of the dyeing of the acid azo colours to which reference has already been made, where, for example, practically the same amount of acid must be used for 3 per cent. and 0.3 per cent. colouring matter.

On examining under the microscope the dyed fents Nos. 1, 5, 9, mordanted with decreasing amounts of chromium tartrate only, an appearance was observed which seems to be very instructive. In addition to colourless fibres there were others presenting all shades, varying from a pale to a dark brownish pink; sometimes even the same fibre showed equally great differences, while others were dyed throughout. The fents mordanted with the addition of acid and then dyed had a much better appearance, although even in these all the fibres were not equally dyed. It was remarked, too, that the pink was of a yellower hue. No formation of precipitated lake could be noticed in either case. With the chromic oxide mordant hitherto examined, we have not noticed the production of an absolutely level colour (*i.e.*, microscopically examined), and although the tartrate and oxalate give quite satisfactory dyes, bichromate of potash gives better results in this respect.

In a subsidiary experiment bearing upon this point, 10 grms. wool were boiled with 600 cc. water and equivalent amounts of chrome alum (0.28 grms.) and alizarin (1 grm., 20 per cent. paste), with the result that a somewhat deep yellow coloured and turbid liquor was obtained, which was almost neutral. The wool had, therefore, practically absorbed the whole of the  $\text{SO}_3$  ( $=0.0672$  grms.), and thus permitted the alizarin to combine with the chromic oxide. The colour thus obtained was a dull uneven Bordeaux, with yellow and pink specks, corresponding to the amount of sulphuric acid which the individual fibres had absorbed. A much better result was obtained by using chromium tartrate corresponding to the 0.28 grms. chrome alum.

In another experiment, in which the alizarin was dissolved in an equivalent amount of ammonia, a poor, bare colour was obtained, of scarcely half the depth of the previous one, a result which shows how greatly the wool needs acid. If sodium alizarate had been used instead of the ammonium salt, probably no reaction at all would have occurred.

**Experiment 38.**—Before recognising chromium tartrate and oxalate as the best chromic oxide mordants, this experiment was made in order to see if an increase of oxalic acid was necessary with a small amount of chrome alum (4 per cent.), and is mentioned here because it also bears upon the point examined in the foregoing experiments.

Wool was mordanted with—

- |      |  |
|------|--|
| (1.) | 4 per cent. chrome alum + 1 per cent. oxalic acid. |
| (2.) | " " " + 1.5 " "                                    |
| (3.) | " " " + 2.0 " "                                    |
| (4.) | " " " + 2.5 " "                                    |

The mordanted fents were afterwards dyed with excess of logwood (40 per cent.). No. 1 was a very poor colour, almost as bad as if 10 per cent. chrome alum had been used; No. 2 was a little better, No. 3 the best, and No. 4 slightly worse than 3. Now, when using 10 per cent. chrome alum, experiment showed that one must use at least 2 mols.  $=2.52$  per cent. oxalic acid, so that in proportion

one might have expected that for 4 per cent. oxalic only 1 per cent. chrome alum would be needed, whereas this experiment shows that double this amount gives the best colour, an amount which corresponds to  $\text{Cr}_2(\text{SO}_4)_3$ ; 4 mols.  $\text{C}_2\text{H}_2\text{O}_4$ , and which for 10 per cent. of chrome alum would be equivalent to 5 per cent. oxalic acid. When microscopically examined, No. 1 was found to exhibit both white and dull blue fibres; No. 2 was much better, No. 3 better still, but showing both pale and dark blue fibres; No. 4 was worse than 3, and about equal to 2. With too much oxalic acid the colour is a reddish grey.

This experiment shows clearly that the wool fibre demands the use of a certain amount of acid, which must be determined for each special case if one wishes to avoid the production of colours which correspond to Hayez's "couleurs alcalines."

**Experiment 39.**—Six fents of wool (Nos. 1 to 6) were mordanted respectively with 10, 5, 2.5, 1.25, 0.625, and 0.3125 per cent. chrome alum, along with correspondingly decreasing amounts of oxalic acid, *viz.*, in the proportion of 1.5 mols. per 1 mol. chrome alum. Six other fents (7 to 12) were mordanted with the same amounts of chrome alum as above, but each with equal quantities of oxalic acid (0.189 grm.) *i.e.*, constant acidity. The latter gave a fine series of bright colours; the former were dull.

A repetition experiment, in which the fents were dyed with logwood, gave similar results; proportional acidity gave unpleasant grey colours, constant acidity fine blue shades. The results of experiment 37 showed, however, that with small amounts of chrome alum one ought not to use as much acid as for 10 per cent. chrome alum. In another experiment it was found that for 2.5 per cent. of chrome alum, 0.126 grms. oxalic acid ( $=4$  mols.) ought to be used.

All the experiments on this point showed, therefore, that for decreasing amounts of chrome alum one ought to use relatively increasing amounts of oxalic acid, and this explains most satisfactorily why in practice the same amount of mordant is frequently employed for different amounts of dye-stuff, since with proportional reduction of mordant there would have been too little acid in the bath. This custom is nevertheless not strictly rational, in so far that the necessary acidity for the paler shades should rightly be produced by additions of the *assistant acid* rather than by excess of mordant, although in practice the question of economy may intervene.

The need for acids by the wool is also well illustrated in the case of single-bath colours, where for pale shades it is customary to reduce only the amount of colouring matter and keep the rest of the ingredients constant in amount. In a single bath, yellow, for example, in which  $\text{SnCl}_2$ ,  $\text{SnCl}_4$ , oxalic acid, and flavin are employed, a proportional reduction of all the constituents for a pale shade would give a poor colour, but a bright colour is obtained if only the flavin is reduced. In the latter case an excess of mordant is of course used, but its employment preserves the purity and beauty of the pale colour.

### 5. Chrome Alum and Chromic Acid.

In recent years three chromium-chromate mordants have been recommended for cotton and silk by Von Gallois and introduced to the trade as chrome mordants, GA 1, GA 11, GA 111, by Messrs. Meister, Lucius, and Brüning of Hoechst. It seemed desirable, therefore, to try similar compounds for wool. Experiments were made with mixtures of chrome alum and bichromate of potash.

The simplest method to obtain a chromium chromate seemed to be to follow the equation—

On mordanting wool with the above mixture, equivalent to 3 per cent.  $\text{K}_2\text{Cr}_2\text{O}_7$ , the bath quickly became turbid and the experiment was not continued.

Another experiment in which the proportions were in accordance with the equation—

showed this mixture also to be of no use.

*Experiment 40.*—Six woollen fents were mordanted with

(1.) 3 per cent.  $K_2Cr_2O_7$  + 1 mol.  $H_2SO_4$ .

(2.) Chromium sulphate chromate—

(3.) As No. 2 + 1 mol. oxalic acid.

(4.) " + 2 " "

(5.) " + 3 " "

(6.) " + 4 " "

Bath No. 2 decomposed after 10 minutes, No. 3 after 25 minutes, No. 4 after 1 hour, Nos. 5 and 6 remained clear. The appearance of the patterns during the mordanting was as if the oxalic acid had at first simply liberated the chromic acid, which was then taken up by the wool. On dyeing the patterns in quercitron bark No. 1 gave by far the best result, a full brownish orange; the large amount of oxalic acid gave better results than the smaller ones, the shade of orange being greener proportional to the reduction which had occurred. After No. 1 the next best mordant was No. 5.

*Experiment 41.*—This was a repetition of the last experiment, but using tartaric instead of oxalic acid. Here the reduction was still greater, and the greenish orange shades were somewhat fuller, but No. 1 was still the best colour.

*Experiment 42.*—Here woollen fents were mordanted with a mixture of equal mols. chrome alum and chromic acid anhydride both alone and with the addition of increasing amounts of oxalic acid, thus:—

(1.) 3 per cent.  $K_2Cr_2O_7$  + 1 mol.  $H_2SO_4$ .

(2.) One mol. chrome alum + 1 mol.  $CrO_3$  (the Cr equivalent to that in No. 1).

(3.) As No. 2 + 1 mol. oxalic acid.

(4.) " + 2 " "

(5.) " + 3 " "

(6.) " + 4 " "

The result was that although here there was an acid compound present, No. 2 bath decomposed after 20 minutes, No. 3 after 25 minutes, No. 4—6 remained stable. When dyed in quercitron No. 1 appeared the best, No. 5 the next, and No. 6 the palest.

*Experiment 43.*—This was a repetition of the last experiment, using tartaric instead of oxalic acid. Smaller amounts of tartaric acid sufficed to prevent dissociation than in the case of oxalic acid, and the shades were paler and greener. No. 1 was again the best colour.

*Experiment 44.*—In this experiment similar proportions were employed as in No. 42, except that 1 mol. chrome alum + 2 mols.  $CrO_3$  were employed, the amount of chromium being equivalent to that contained in 3 per cent.  $K_2Cr_2O_7$ , with which 1 mol.  $H_2SO_4$  was used. In this case bath No. 2 decomposed after 20 minutes, No. 3 showed a tendency to decompose after 30 minutes, the rest remained clear. With the increase of oxalic acid the yellowish-green colour of the bath gradually gave place to a greenish-violet. In accordance with the fact that here the mordant was richer in  $CrO_3$ , the dyed patterns appeared better than the corresponding ones of experiment 42. No. 1 pattern was still the best, next came No. 4 with 2 mols. oxalic acid.

*Experiment 45.*—This was a repetition of No. 44, using tartaric acid, with the result that the shades were green and fuller. No. 1 was the best.

*Experiment 46.*—This was a similar experiment, but made with the use of 1 mol. chrome alum + 3 mols.  $CrO_3$ , and various amounts of oxalic acid as before. No new feature was developed, and the fact was merely emphasised that the colours improved in proportion as the  $CrO_3$  in the mordant decreased and the  $CrO_3$  increased, but in no case was the result as good as with chromic acid alone. The effect generally gave one the impression that the mordants were simply mixtures.

*Experiment 47.*—This was a repetition of No. 46 with tartaric acid. Here, too, baths Nos. 2 and 3 decomposed, the rest remaining clear. The waste liquor of No. 1 was pale yellow, No. 2 dull yellow, Nos. 3—6 the colour gradually

became greener and the baths appeared to be better exhausted. The mordanted and also the dyed patterns were greener than when oxalic acid was used, which was not able to reduce all the chromic acid until 6 mols. were employed. No. 1 pattern had invariably the best colour. The use of solutions of chromium chromates as mordants for wool seems unpromising. Useful results are only obtained when fairly large amounts of organic acid are used as well, in which case there is no advantage over bichromate of potash. It is well to note that the wool mordanted in the manner described always seemed to have a pleasant soft feel.

In a subsidiary experiment a piece of wool was padded with a solution containing 1 mol. chrome alum + 1 mol.  $K_2Cr_2O_7$  + 2 mols. oxalic acid, dried and steamed; it thus acquired a dull olive grey colour, so that here too the reduction was incomplete. Total reduction occurred, however, if instead of oxalic acid 2 mols. tartaric acid were used, and the wool acquired a violet-greenish-grey colour rather than green, indicating that a chromic oxide salt was present in the fibre rather than chromic hydrate.

In comparing the two methods of fixing the mordant by steaming and by boiling it was generally found that in the former the presence of less acid was needed than in the latter, evidently because of the greater concentration of the mordant solution in the former case. If in the last-mentioned experiment the acid was entirely omitted, the fent acquired a brownish-green colour, pointing to the presence of both  $Cr_2O_3$  and  $CrO_3$ , and there was apparently total fixation of the mordant.

*Experiment 48.*—This experiment was suggested by the foregoing observation. Fents were mordanted in the usual manner with a mixture of chrome alum and bichromate of potash, equivalent to 3 per cent.  $K_2Cr_2O_7$ , and which we might consider as a chromium-chromate-sulphate presented to the wool, thus:—

The different fents were mordanted with—

(1.)  $Cr_2(SO_4)_3 + K_2Cr_2O_7$ , equivalent to 3 per cent.  $K_2Cr_2O_7$

(2.) As No. 1 + 2 mols. oxalic acid.

(3.) " + 3 " "

(4.) " + 4 " "

(5.) " + 5 " "

(6.) " + 6 " "

Bath No. 1 had a yellowish colour reminding one of  $K_2CrO_4$ , No. 2 similar, No. 3 a peculiar dichroic yellow-violet appearance, Nos. 4, 5, 6 all greenish violet. At 70° C. No. 1 became turbid, the others remained clear.

The mordanted fents had the following appearances: No. 1 pale reseda colour, Nos. 2—4 rapidly less yellow and more green, No. 5 a pleasing greyish green, No. 6 the most pronounced green of the series.

The samples were dyed with 30 per cent. logwood, which gave somewhat deep black-blue colours, Nos. 2 and 3 being the best, with more than 4 mols. oxalic acid the colours became much paler. The amount of water requisite for the mordanting process by the boiling method demands, therefore, the use of a little more acid.

In this connection two other experiments may be cited here. Wool was mordanted with chromium equivalent to 3 per cent.  $K_2Cr_2O_7$  by means of the following mixtures:—

(1.) 2 mols.  $Cr_2(SO_4)_3$  + 1 mol.  $K_2Cr_2O_7$ . ( $=K_2SO_4 + 5SO_3 + 2(Cr_2O_3 \cdot CrO_3)$ ).

(2.) 1 mol.  $Cr_2F_6$  + 3 mols.  $K_2Cr_2O_7$ . ( $=6KF + Cr_2O_3 + 6(CrO_3)$ ).

Of these the first seems to have been already tried by Lepetit; both are quite arbitrary equations, and are only provisionally regarded as possibly occurring, e.g., the first would only take place if the wool absorbs the 5 mols.  $H_2SO_4$ ; the second was merely suggested by a desire to render the  $HCl$  harmless, and to obtain a more neutral mordant. The amount of  $SO_3$  to be absorbed in the first case would be 0.16 gms. less, therefore, than is possible. The intention was to find a mordant which would be taken up by the wool as completely as possible.

No. 1 bath was barely acid, and was exhausted apparently very well, the wool seeming to attract merely chromic acid in the first instance, but becoming browner at a later stage, as expected, by the fixing of  $\text{Cr}_2\text{O}_3 \cdot \text{CrO}_3$ . After  $\frac{1}{2}$  hour at 71° C. the bath became slightly turbid through the precipitation of basic chromic sulphate, but on boiling it again became clear. No. 2 bath was slightly acid to litmus, became turbid after 25 minutes at 60° C., but afterwards cleared again; it was of a pale yellow colour, and seemed fairly well exhausted, the wool acquiring the colour of  $\text{Cr}_2\text{O}_3 \cdot \text{CrO}_3$ . When dyed in alizarin pleasing claret-reds were obtained, No. 1 slightly paler but brighter and clearer than No. 2. Slight additions of acid to the mordant bath would probably have given better results even, and further experiments in this direction might be valuable, especially since the mordant baths are so well exhausted.

In order to gain some idea of the nature of the interaction of 2 mols. chrome alum and 1 mol. bichromate of potash a solution of the mixture was allowed to evaporate slowly over sulphuric acid. At first yellow prismatic crystals were formed, in colour more like  $\text{K}_2\text{Cr}_2\text{O}_7$  than  $\text{K}_2\text{Cr}_2\text{O}_7$ ; then appeared violet octahedra of chrome alum, some showing a tendency to become cubical; curiously enough some violet red prismatic crystals were also noticed, as well as colourless dendritic crystals. Finally a deep grass-green indistinctly crystalline mass was produced, evidently a mixture; here and there it was turbid, probably from the presence of  $\text{Cr}_2\text{O}_3 \cdot \text{CrO}_3$ . The amount of each substance was too small to attempt separation and analysis. Possibly the chrome alum by loss of  $\text{H}_2\text{SO}_4$  had become basic and liberated chromic acid, and also furnished  $\text{K}_2\text{SO}_4$ . The grass-green mass might simply be a mixture of  $\text{Cr}_2(\text{SO}_4)_3$  and chromic acid, and the yellow crystals  $\text{K}_2\text{SO}_4$  contaminated with a little chromic acid. Formation of potassium trichromate might also be possible. A simpler and possibly truer explanation may be represented by the following equation:—

If a similar evaporation experiment be made with equal mols. of chrome alum and  $\text{K}_2\text{Cr}_2\text{O}_7$  one obtains at first, in addition to undecomposed chrome alum, orange yellow crystals and a brown resinous mass insoluble in water ( $\text{Cr}_2\text{O}_3 \cdot \text{CrO}_3$  (?)). If the mixture is repeatedly mixed with water and evaporated again and again, there remains finally a brown mass, which, when dissolved in water, separates into an acid yellowish-green part (a solution containing chromic oxide and chromic acid), and an insoluble portion consisting of  $\text{Cr}_2\text{O}_3 \cdot \text{CrO}_3$ , possibly according to the following equation:—

Of these products the first by loss of  $\text{H}_2\text{SO}_4$  on dilution with water would yield an insoluble compound.

### C. Chromium Chloride.

Although the behaviour of this salt towards wool has already been referred to, one or two experiments made with it with the addition of oxalic and tartaric acid remain to be very briefly described.

**Experiment 49.**—Samples of wool were mordanted with the following:—

- (1.)  $\text{Cr}_2\text{Cl}_6$  (equivalent to 10 per cent. chrome alum).
- (2.) " + 1 mol. oxalic acid.
- (3.) " + 2 " "
- (4.) " + 3 " "
- (5.) " + 4 " "
- (6.) " + 5 " "

With the increased additions of acid the baths became more and more exhausted. In the mordanted condition No. 1. fent had a cream colour, Nos. 2 and 3 more greyish, Nos. 4—6 more and more greenish-grey, No. 6 appearing

very well mordanted indeed. When dyed with alizarin, however, No. 1 with 1 mol. oxalic acid gave the best colour, while No. 1 scarcely dyed at all.

**Experiment 50.**—In this trial the following mordants were used:—

- (1.)  $\text{Cr}_2\text{Cl}_6$  (equivalent to 10 per cent. chrome alum).
- (2.) " + 2 mols. tartaric acid.
- (3.) " + 3 " "
- (4.) " + 4 " "
- (5.) " + 5 " "
- (6.) " + 6 " "

All the baths remained clear; No. 1 retained its original colour, Nos. 2—6 ranged gradually from red green to pure green, and became more and more exhausted, so that No. 6 was finally almost colourless. In the mordanted condition No. 2 appeared greenish-grey, No. 3 similar, but deeper in colour, No. 4—6 pure green. When dyed in alizarin cyanin No. 1 gave a very poor colour, No. 2 the best, while Nos. 3—6 gave paler colours, although from the appearance of the mordanted fents a better result even than that of No. 2 was to be expected. No doubt this defect is due to the increased amount of acid absorbed by the wool, and would be remedied by increasing the amount of calcium acetate added to the dye-bath.

In this experiment the addition of 2 mols. tartaric acid gave the best result, and corresponding to this, in another experiment, 4 mols. cream of tartar gave the best colour.

It is well to emphasise the fact that the behaviour of chromium chloride towards wool when used alone is very different indeed from that of chrome alum; with chrome alum nearly the whole of the chromium disappears from the bath, whereas with chromium chloride the opposite is the case: the major portion remaining in the bath and scarcely mordanting the wool at all.

Chromium nitrate behaves like the chloride, yielding no result except with the use of organic acids, even though there is no dissociation of the salt.

In the case of cotton chrome alum and even chromium acetate give poor results, while the chloride and nitrate, especially in the form of basic salts, are very satisfactory. Witt has also referred to the unsuitability of chromium chloride as a mordant for wool.

### D. Chromium Fluoride.

In recent years this salt has been much recommended as a mordant for wool, and is considered to give up to the wool pure chromic hydrate. Some employ along with it, as an assistant, cream of tartar, others oxalic acid, e.g., 4 per cent. chromium fluoride and 2 per cent. oxalic acid.

**Experiment 52.**—Wool (10 grms.) was mordanted in the ordinary manner with 4 per cent. chromium fluoride and 600 cc. water, previously adding 1 cc. normal HCl to neutralise the alkalinity of the water and the wool.

As in the case of chrome alum the bath decomposed already below 100° C., and the mordanted wool had a yellowish-green colour. The waste liquor required 4.4 cc. normal NaOH, i.e., much more than chrome alum, from which one may calculate that only 33.42 per cent. of the salt had been decomposed. These facts show that like chrome alum, chromium fluoride also dissociates, and this accounts for the necessity of employing organic acids along with the fluoride, a point which is distinctly recognised in practice, and we may reasonably ask then, does the fluoride possess, after all, any real advantage over chrome alum? When a chromic oxide mordant is required, one may obtain similar results by using chrome alum along with 2 mols. tartaric or oxalic acid, or better still to use chromium tartrate or oxalate.

If one considers that it will scarcely be necessary to use more chromium oxalate than is equivalent to 4 per cent. chrome alum, surely with the present low price of oxalic acid the cost of chromium oxalate need not be reckoned as an impediment against its general employment, e.g., with alizarin colours.

### Conclusion.

The nature of the reactions which occur when wool is mordanted with solutions of metallic salts has long been the subject of comment and discussion by various writers on dyeing. Gouffreville in his "*L'art de la teinture des laines*," (1849), says: "The mordants are for the most part basic salts: with the use of cream of tartar there is fixed on the fibre a tartrate of the metal, and thus tartaric acid enters into the composition of the colour lake and the defect of rubbing-off is avoided. Acids increase the power of diffusion and lessen the affinity of the wool for the mordant."

Road and Thénard (*Ann. de Chimie*, 74, 267) concluded that when wool is immersed or even boiled in a solution of alum, the latter is not decomposed but absorbed by the wool unchanged, and can be removed therefrom by boiling several times with water. When wool is boiled with cream of tartar these chemists state that the fibre takes up tartaric acid, leaving in the bath neutral tartrate of potash. When boiled with alum and tartar they suppose that the wool may contain undecomposed alum as well as the tartrates of alumina and potash and free tartaric acid.

Chevrel found that wool absorbed alum from its solution, and retained the unchanged salt or some other aluminium compound not removable by washing.

Bolley states that alum solution gives up a sub-salt to the fibre steeped in its solution, leaving the latter more acid.

Girardin, in his "*Leçons de chimie élémentaire*," IV., p. 410, 6th edit., says: "It is certain that mordants and colouring principles react chemically upon each other to produce insoluble coloured compounds or lakes, which permeate wool and silk throughout their mass, whereas in the case of vegetable fibres they remain on the external surface, and although the part played by the fibre is not definitely understood, one is disposed to admit that its rôle is purely physical."

Schützenberger ("*Traité des matières colorantes*, I., p. 149) says: "Many salts, among others alums, are precipitated from their solutions by wool and retained with energy by virtue of some special attractive force."

Nietzki, in his *Chemie der organischen Farbstoffe*, p. 13, (p. 15 of English translation), says: "This peculiar property of dyeing on metallic mordants has as yet had no satisfactory explanation. If cotton mordanted with alumina or oxide of iron is placed in an alizarin bath, the lake is precipitated and enters into intimate combination with the fibre. It is probable, however, that the author is here referring to the different behaviour of the two classes of oxides  $RO$  and  $RO_2$  than to the real nature of the dye upon the fibre."

The views, relative to the theory of mordanting, to which our experiments lead us may be briefly summarised as follows:—

The necessity of employing acids, and preferably organic acids, points undoubtedly to the prevention of a precipitation in the fibre of oxide or a basic salt. We are driven to the conclusion, therefore, that during the mordanting process with metallic salts, the wool does not attract either oxides or basic salts, but, on the contrary, acid salts, and we refer here to compounds of the sesquioxides only. Primarily the wool seems to exert an attraction for the acid of the mordanting salt, and to prevent the otherwise inevitable precipitation of a basic salt the presence of an organic acid is beneficial. Precipitation by the ammonia given off through decomposition of the wool is prevented in like manner. The appearance of a well mordanted wool, too, does not point to the presence in the fibre of a hydrate but a salt.

Although during the process of dyeing mordanted wool the bleeding out of acid into the dye-bath was invariably noticed, it is not unreasonable to assume, until evidence to the contrary is adduced, that at least a portion of the acid remains in combination with the coloured body on the wool, a view which seems to be supported by the existence of the single-bath method of dyeing where the solutions are invariably acid.

It appears to us very probable that when wool is mordanted with a metallic salt, both the amido and carboxyl groups of the fibre come into play, the former attracting the

acid of the mordanting salt while the latter attracts the base, the end result being that an acid salt is fixed in the fibre. Excess of acid or the presence of organic acids is necessary, as already stated, to prevent the more or less superficial precipitation of a basic salt, and the mordanting salt remains sufficiently long in solution for it to penetrate the fibre till a wool compound is formed which is thus equally distributed throughout the mass of the fibre. We may regard the wool fibre as being more or less analogous to the cotton fibre when prepared with oil by the Turkey-red process; here fibre and fixing agent for the mordant are separate, but in wool these two elements are united in one and the same substance, namely, the fibre itself, so that in alizarin red dyed wool we have, a complex lake in which the fibre itself is a constituent element.

Compared with studies in cotton dyeing, those in wool dyeing are much more difficult, because it is not possible to repeat the reactions apart from the fibre as in the former case. In dyeing cotton the fibre appears simply to be the carrier of the metallic hydrate or insoluble basic salt, and this both in the beaker and on the fibre will combine with the colouring matter. With wool, however, it is quite different, for example, in the single-bath method. Here we employ together, the metallic salt, organic acid, and colouring matter. The same mixture may be boiled for several hours apart from the fibre, but no reaction ensues, and no colour is produced, not even when calculated amounts of sodium hydrate are added. Even when wool is present no lake is at once formed, and the dye-bath does not appear to contain the colour as such, but gradually as the temperature rises the colour is developed and indeed within the fibre.

We can scarcely claim to have fully proved the truth of the views just now expressed, for there is no doubt that the reactions which have occupied our attention are of a complex character, but we trust that the various observations recorded throughout the paper may be useful to others working on the same subject, and that our communication, so far as the theory of mordanting wool is concerned, may be regarded as an attempt to solve experimentally a very difficult problem.

### DISCUSSION.

MR. RAWSON thought it was not possible to determine the amount of acid taken up by the fibre by estimating the acid left in the bath; it could not well be determined directly, however, as the amount of sulphur it contained was but small relatively to that contained in the wool itself. Was the wool washed thoroughly before its acidity was determined? And was it possible to distinguish between the acid present as such in the wool and that present in combination with chromium oxide? It was said that a non-oxidising mordant was desirable; potassium bichromate, however, would not destroy indigo, although chromic acid would. And the desirability had been emphasised of a mordant which could be completely exhausted, and not merely, like bichromate, to the extent of one-third; this was not practically of much importance, as the bichromate bath could be used over and over again, and thus nearly exhausted, particularly when acid was added from time to time. The bad results obtained on dyeing the wool mordanted with chrome alum was, as one would expect, due to an irregular absorption of the dye by the wool. He thought that the ammonia, which was found when wool was boiled, might have played a part in the formation of the precipitate in the dye-bath, and so might any soap or alkali still present in the wool. What were the dyes that had been experimented with.

MR. RICHARDSON thought it very desirable to ascertain the exact amido character of wool; and Prof. Hummel had stated that the ammonia liberated from the wool played some part in the mordanting process; the fact that it yielded much ammonia when boiled with caustic potash or baryta showed that it must be rich in groups of an acid-amide character. He thought it would be easy to ascertain if the acid existed in the free form in the fibre; if so, the wool would dye blue with Congo red. If not it might have formed ammonium sulphate with ammonia derived from the

amido groups, and would be closely retained between the septa of the porous fibre; and in this case its amount might be determined by treating with cold potash solution and estimating the ammonia formed by Nessler's test, and any deficit from the amounts equivalent to the sulphuric acid in the fibre would show that some of the acid must be present in the free state. Again, if free sulphuric acid were present, its presence would be indicated by a blackening of the wool when dried. He would like to see a better proof of the presence of free acid in the fibre.

Dr. CONEX suggested that the decomposition of the chrome-alum solution by the wool fibre might be due to two causes, firstly, to dialysis of the salt through the fibre, in which case the sulphuric acid would pass through and a basic sulphate be left behind, and, secondly, to absorption of the sulphuric acid thus set free by certain constituents of the wool. This would account for the gradual precipitation of the basic sulphate as the bath was heated up, and the absence of free sulphuric acid in the bath.

It would be interesting to try whether from a solution of chrome alum in a dialyser, sulphuric acid would diffuse out, leaving a basic sulphate of chromium, which would be precipitated on boiling. If hydrochloric acid had little affinity for the wool fibre this would account on the above hypothesis for the absence of mordanting properties of chromic chloride. In what form was the sulphuric acid in combination with the fibre? He thought that the cause of the colour changes on heating chrome alum solution might be other than that suggested by the authors.

Mr. A. G. PERKIN asked if any experiments had been made with Vignon's amido-cellulose, a substance prepared by heating cotton with ammonia under pressure, and having considerable resemblance to wool. Probably a study of its reactions with mordants would throw further light upon the results under discussion.

Prof. HUMMEL, in reply, said that the experiments recorded in the paper were carried out by Mr. Liecht. The wool used had been thoroughly washed, and the amount of sulphuric acid required to neutralise the alkali in it had been determined. Any such impurity was certainly not the cause of acid absorption by the fibre. The only way to distinguish the acid fixed as such from that combined with chromium as a basic salt was by repeated boiling or prolonged steeping in water, when the acid present as such would slowly "bleed" out. It was true that bichromate did not destroy indigo, but with more sensitive colours, such as alizarin-blue, some other non-oxidising mordant was required. It was also true that it was not absolutely necessary that a bichromate bath should be exhausted, but, after replenishing and using it once or twice, the dyer no longer knew how much chromium it contained, and so could not work in a scientifically correct manner. The dyes used were chiefly logwood, quercitron bark, alizarin-blue, and alizarin. Some of the sulphuric acid absorbed by the fibre would no doubt be neutralised by ammonia given off from the wool. The wool had not been dried to see if blackening ensued. With respect to the cause of the colour changes exhibited by chrome-alum solution on heating, he had merely quoted the opinion of others. Mr. Perkin's suggested experiment had not been tried, the experiments having been concluded before the appearance of Vignon's paper. He had recently compared the behaviour of cotton treated with albumin with that of wool, and found them to be generally similar; for example, the cotton thus treated could be dyed a cochineal scarlet in single bath, after the manner adopted for wool.

Mr. H. R. PROCTOR said that hide fibre would absorb either acid or alkali from dilute solution, together with much water which swelled the fibre, but either could be removed by sufficient washing, so that chemical combination could hardly have occurred. Sodium chloride reduced the swelling produced by acid, and at the same time dehydrated the fibre to a much greater extent than when acid was not present.

As regards the absorption of aluminium salts, the researches of Reimer, conducted much on the lines of those

just described by Prof. Hummel, had shown that from alum, aluminium sulphate was absorbed, either as such or in a slightly basic form.

An interesting process of leather manufacture was now largely employed in the United States in which the active agent was chromic acid, which was afterwards reduced on the fibre by sulphurous acid. The leather produced was pale green, and extraordinarily resistant, even to boiling water. By means of chrome alum a leather could be produced precisely similar in appearance, but no more resistant to boiling water than ordinary alumed leather, while by using a basic chloride it was stated that the result was similar to that produced by reduction on the fibre.

## Scottish Section.

J. Stanley Muir, Chemical Laboratory, University of Glasgow.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman*: R. Irvine. *Vice-Chairman*: J. Clark. *Committee*: R. Cox, C. A. Fawcett, D. Harris, E. Ostler, R. Pullar, and H. Rose.

## SESSION 1893-94.

Glasgow:—

May 1st.—

Mr. R. R. Tatlock and Mr. R. T. Thomson. "On the Suitability of Water for Domestic Purposes as shown by Chemical Analysis."

Discussion, "The Production of Gas from Paraffin Oils" (this Journal, 1894, 241-247).

Meeting held in the New University Buildings, Edinburgh, on April 3rd, 1894.

MR. R. IRVINE IN THE CHAIR.

## THE EFFECT OF THE SALINE CONSTITUENTS OF WATER ON THE CHARACTER OF BEER.

BY J. B. READMAN, D.S.C., F.R.S.E.

IN a recent\* treatise on the Science of Brewing, the following passage occurs:—

"Having now considered the classes of water which are in general use, it will be well before describing their treatment in detail, to survey the present state of our knowledge concerning the influence of the saline constituents in relation to the brewing process. It is a somewhat humiliating fact that our knowledge on this important matter is still pretty well limited to the practical teaching of the brewhouse experience." Again, in the Canon lectures on Brewing delivered 20 years ago (1874) by Dr. Charles Graham, it

\* A Text Book of the Science of Brewing, by Morris and Morris (E. and F. N. Spon).

is stated:—"There is a remarkable discrepancy of opinion with reference to the influence of these chlorides of sodium, potassium, magnesium, calcium, and so on, and their sulphates, among the brewers of Europe. If you ask an able brewer in Germany, he will tell you he looks on these mineral salts as bad, but if you ask a Burton brewer, or many English brewers, they will tell you that they look upon them as being almost the sheet anchor of their pale ale system. What then is the right action of these mineral salts in the mashing process?"

It is with the object of endeavouring to throw some light on this important subject that the following experiments, 13 in all, have been undertaken.

The 13 mashings, boilings, and fermentations were all performed with the same quality and quantity of malt, hops, and yeast. There were 12 artificially prepared waters used, beginning with distilled water alone, as the first of the series, while the 13th was carried out with Edinburgh gravitation water. In the 12 cases the various salts were dissolved in distilled water, making up the set of experiments as under:—

- No. 1. Di-stilled water.
- No. 2. Distilled water, containing carbonate of lime in  $\text{CO}_2$  equal to 50 grains  $\text{CaCO}_3$  per Imperial gallon.
- No. 3. Distilled water, containing chloride of calcium equal to 50 grains  $\text{CaCl}_2$  per Imperial gallon.
- No. 4. Distilled water, containing sulphate of lime equal to 50 grains  $\text{CaSO}_4$  per Imperial gallon.
- No. 5. Distilled water, containing carbonate of magnesia in  $\text{CO}_2$  equal to 50 grains  $\text{MgCO}_3$  per Imperial gallon.
- No. 6. Di-stilled water, containing chloride of magnesium equal to 50 grains  $\text{MgCl}_2$  per Imperial gallon.
- No. 7. Distilled water, containing sulphate of magnesia equal to 50 grains  $\text{MgSO}_4$  per Imperial gallon.
- No. 8. Distilled water, containing chloride of sodium equal to 50 grains  $\text{NaCl}$  per Imperial gallon.
- No. 9. Distilled water, containing carbonate of soda equal to 50 grains  $\text{Na}_2\text{CO}_3$  per Imperial gallon.
- No. 10. Distilled water, containing nitrate of potash equal to 50 grains  $\text{KNO}_3$  per Imperial gallon.
- No. 11. Distilled water, containing salts to imitate Burton water, composed of—

	Grains.
Sulphate of lime.....	70.99 $\text{CaSO}_4$ per Imperial gallon.
Carbonate of lime.....	4.04 $\text{CaCO}_3$ per Imperial gallon.
Carbonate of magnesia..	5.88 $\text{MgCO}_3$ per Imperial gallon.
Sulphate of potash.....	0.96 $\text{K}_2\text{SO}_4$ per Imperial gallon.
Sulphate of soda.....	13.30 $\text{Na}_2\text{SO}_4$ per Imperial gallon.
Chloride of Sodium.....	9.12 $\text{NaCl}$ per Imperial gallon.
Ferric oxide.....	1.13 $\text{Fe}_2\text{O}_3$ per Imperial gallon.

- No. 12. Edinburgh gravitation water.
- No. 13. Distilled water, containing sulphate of potash equal 50 grains  $\text{K}_2\text{SO}_4$  per Imperial gallon.

Before going into the details of the several mashings, &c., it will be well, perhaps, in the first place, to say something about the malt and the hops which were used in the experiments.

First. The malt was made from Scotch barley weighing 56 lb. per bushel. It contained the following percentages of nitrogen, ash, and phosphoric acid:—

#### ANALYSIS OF THE MALT.

	Per Cent.
Total nitrogen.....	1.85
Comprising nitrogen soluble in distilled water, at 150°—160° F.....	0.85
Comprising nitrogen insoluble in distilled water, at 150°—160° F.....	1.00
Total phosphoric acid ( $\text{P}_2\text{O}_5$ ).....	0.98
Comprising $\text{P}_2\text{O}_5$ soluble in distilled water, at 150°—160° F. (wort).....	0.73
Comprising $\text{P}_2\text{O}_5$ insoluble in distilled water, at 150°—160° F. (draff).....	25
Total ash in malt.....	2.21
Comprising, soluble ash in extract (wort).....	1.32
Comprising, insoluble ash in residue (draff).....	0.92
In total ash—	Per Cent.
Silica.....	0.56
Lime.....	0.10
Magnesia.....	0.21
Phosphoric acid.....	0.98

	Per Cent.
Extract (wort) soluble in distilled water at 150°—160° F.....	69.36
Insoluble matter (draff) in above.....	27.90
Moisture.....	2.74
	100.00

The hops were "East Kent" and gave on analysis the following results:—

#### ANALYSIS OF THE HOPS (EAST KENT).

	Per Cent.
Total nitrogen in hops.....	2.68.
Comprising nitrogen soluble in boiling water....	0.67
Comprising nitrogen insoluble in boiling water.....	2.01
Total phosphoric acid in hops.....	1.09
Comprising $\text{P}_2\text{O}_5$ soluble in boiling water.....	0.64
Comprising $\text{P}_2\text{O}_5$ insoluble in boiling water.....	0.45
Total ash in hops.....	8.55
Comprising ash soluble in boiling water.....	4.57
Comprising ash insoluble in boiling water.....	3.98
Ash contains—	
Silica.....	1.80 soluble 0.57 insoluble 1.23
Lime.....	1.47 " 0.18 " 1.29
Magnesia.....	0.45 " 0.25 " 1.21
Phosphoric acid... ..	1.00 " 0.61 " 0.45

	Per Cent.
Extract (soluble in boiling distilled water).....	24.15
Insoluble matter.....	63.93
Moisture.....	11.92
	100.00

The procedure was similar in all the experiments, but owing to an accident only 11 of them could be commenced on the same day, the other two (Nos. 8 and 13) had to stand over until the following day, when they also were begun under precisely similar conditions as the rest.

The following is an outline of the general treatment. Six-sevenths of a lb. (= 6,000 grains) of Scotch malt in the form of grist was mashed in 26,000 grains of water.

The water was first of all heated to 160° F. in copper pans. The burner was removed and the grist then rapidly stirred in. The temperature of the mixture fell to 145° F., but was gradually raised until it reached 157° F., at which temperature it was maintained until the completion of the mash.

The mash was now filtered through cloth bags until 16,000 grains of liquor had passed through clear. To each of the worts thus obtained 5,000 measured grains of the original water were added before boiling, thus making up a volume of 21,000 grains.

The draffs left on the cloth filters were washed with hot water until all the soluble matters were removed, the filtrates were thrown away, and the washed and drained draffs were dried and weighed.

The entire time occupied in the mashing process from the first introduction of the grist to the filtration, was an hour and a half, except in two cases—viz., Nos. 5 and 9—carbonate of magnesia and carbonate of soda respectively. When, owing to the liquors, both showing the starch reaction with iodine, the time was extended to two hours.

In the case of the carbonate of magnesia it is well to note that before the expiry of two hours the starch reaction had ceased, but the carbonate of soda experiment gave the reaction to the last. Both experiments filtered badly, and the liquors came through muddy and thick.

The worts were now simultaneously boiled for 1½ hours with 100 grains of hops each, and then rapidly filtered through cloth bags, as before, the liquors being returned to the filters till clear and bright.

The spent hops on the filters were washed with boiling distilled water, and the washings were added to the boiled wort until the latter occupied a volume of 16,000 grains.

The hops were further washed to remove all soluble matters, they were then drained and dried.

The gravities and the temperatures were now taken, and 500 measured grains were removed from each of the boiled worts and placed in sterilised test-tubes for preservation.

The fermentations were all commenced on the same days that the mashings and boilings were undertaken. Flasks holding about 26,000 grains were employed for the purpose; they were provided with india-rubber corks, through which passed a Fahrenheit thermometer and a safety tube for the escape of the carbonic anhydride.

The flasks were all placed in a shallow tin tray, which contained about 2 inches of water—and the temperature was maintained by an Argand lamp kept at a distance of 2½ feet from the tray.

Eleven of the fermentations occupied 9 days, and two of them 8 days.

Full details as to the quantity of malt, hops, and yeast employed, as well as to the original gravities and temperatures, and rates of alternation, are to be found in the description of each experiment which follows.

## No. V.—CARBONATE OF MAGNESIA WATER.

(50 grains  $\text{MgCO}_3$  to gallon dissolved in  $\text{CO}_2$ )

6,000 grains ( $\frac{1}{2}$  lb.) Scotch malt { Temperature from 145°  
F. gradually increased  
to 157° F. Diastatic  
action very slow.  
26,000 „ of above water { Extreme frothing.  
Duration of mash,  
1.45 hours.

Specific gravity of wort from above at 60° F., 1.060.5.

Volume of wort 15,500 grains, to which were added  
5,000 grains of original water, boiled for 1½ hours with  
100 grains E. Kent hops, filtered very badly and very  
muddy.

Total filtrate 5,500 grains.—500 grains sterilised.

5,000 grains fermented with 50 grains yeast.

Date.	Temperature.	Specific Gravity.	Fall in Gravity.

			35

Weight of spent hops (dry)—72 grains.

Analysis of Beer.	Per Cent.	Grains per Gallon.
Alcohol.....	3.73	..
Total solids (extract).....	7.055	49.875
Nitrogen.....	0.087	..
Ash.....	0.310	..
Lime.....	..	..
Magnesia.....	..	..
Phosphoric acid.....	0.067	..
Acidity as lactic acid.....	0.144	..
Silica.....	0.004	..
Specific gravity at 60° F.....	1.021.1	..

Let us now consider some of the points brought out  
by the experiments, taking them up in the following  
order:—

1. Diastatic action.
2. The colour and clearness of the wort filtered from the draff and then boiled with hops.
3. The attenuation.
4. The settling and clarification of the beers.
5. Colour of the beers.
6. Analyses of the beers.
7. Condition, flavour, odour, and stability of the beers.
8. Weights of the residues.

## 1. The Diastatic Action.

Except in the two cases previously referred to (carbonate of magnesia and carbonate of soda) the action was completed in less than an hour: the carbonate of magnesia water, however, took nearly two hours, while the mash prepared with carbonate of soda water had to be filtered incomplete. It is thus evident that the diastatic action is impeded by both these salts, but especially so by carbonate of soda.

This is also true, but to a much less extent, with carbonate of lime water.

## 2. The Colour and Clearness of the Wort filtered from the Draff and then boiled with Hops.

All the worts, while hot, filtered clear and bright, except those prepared with carbonate of magnesia and carbonate of soda waters, respectively, which were both slow in filtering and gave muddy filtrates.

After boiling with the hops and filtering, specimens from each of the worts were sterilised and are in test tubes and in the small flasks on the table for your inspection. Regarding their colour, after a good deal of comparison, both by reflected and transmitted light, I consider that the following is the order of paleness.

- No. 1.—Distilled water. The palest wort.  
 „ 13.—Sulphate of potash water.  
 „ 7.—Sulphate of magnesia water.  
 „ 4.—Sulphate of lime water.  
 „ 6.—Chloride of magnesium water.  
 „ 12.—Edinburgh gravitation water.  
 „ 11.—Imitation Burton water.  
 „ 10.—Nitrate of potash water.  
 „ 3.—Chloride of calcium water.  
 „ 8.—Chloride of sodium water.  
 „ 2.—Carbonate of lime water.  
 „ 5.—Carbonate of magnesia water.  
 „ 9.—Carbonate of soda water, the darkest.

## 3. The Attenuation.

During the fermentations, which occupied nine days, except in the beers prepared with chloride of sodium and sulphate of potash, which were completed in eight days the worts attenuated in the following order :—

No.	—	—	Loss in Gravity.
4	Sulphate of lime water .....	48° F. 72° F. 1.059 to 1.012	47.0
6	Chloride of magnesium water ....	48° F. 71° F. 1.058 to 1.012	46.0
1	Distilled water .....	48° F. 73° F. 1.057.5 to 1.012	45.5
5	Carbonate of magnesia water.....	48° F. 70° F. 1.065 to 1.021	44.0
11	Barton water .....	48° F. 70° F. 1.060 to 1.016	44.0
2	Carbonate of lime water .....	48° F. 72° F. 1.051.5 to 1.009	42.5
7	Sulphate of magnesia water.....	48° F. 71° F. 1.058 to 1.016	42.0
3	Chloride of calcium water.....	48° F. 72° F. 1.057 to 1.015	41.0
9	Carbonate of soda water .....	48° F. 73° F. 1.054 to 1.015	39.0
12	Edinburgh water .....	48° F. 72° F. 1.054 to 1.015	39.0
8	Chloride of sodium water .....	52° F. 71° F. 1.056 to 1.018	38.0
13	Sulphate of potash water .....	50° F. 73° F. 1.055 to 1.020	35.0
10	Nitrate of potash water .....	48° F. 70° F. 1.052 to 1.019	33.0

The beers, after fermentation, were decanted from the yeast into bottles and firmly corked, and were left at rest for two weeks to deposit the floating yeast and clarify.

## 4. The Settling and Clarification of the Beers.

About a fortnight after the beers were made they were examined to see which had cleared the most completely; the following was observed :—

Beer made with—

- No. 1.—*Distilled water*.—Almost clear.  
 „ 2.—*Carbonate of lime water*.—Muddy.  
 „ 3.—*Chloride of calcium water*.—Fairly clear.  
 „ 4.—*Sulphate of lime water*.—Very clear.  
 „ 5.—*Carbonate of magnesia water*.—Clear, but very dark in colour.  
 „ 6.—*Chloride of magnesium water*.—Cloudy.  
 „ 7.—*Sulphate of magnesia water*.—Cloudy.  
 „ 8.—*Chloride of sodium water*.—Cloudy.  
 „ \*9.—*Carbonate of soda water*.—Clear, but very dark.  
 „ 10.—*Nitrate of potash water*.—Slightly cloudy.  
 „ 11.—*Imitation Burton water*.—Slightly cloudy.  
 „ 12.—*Edinburgh gravitation water*.—Almost clear.  
 „ 13.—*Sulphate of potash water*.—Cloudy.

The beers were allowed to settle a few days longer, and exactly one month from the date of the mashing process they were syphoned off from the settling-bottles to the set of 8-oz. bottles you see on the table, and which were then corked and sealed.

## 5. Colour of the Beers.

The most coloured of all are—

No. 5, carbonate of magnesia, and the next No. 9, carbonate of soda (which became cloudy when syphoned into the smaller bottles). No. 2, carbonate of lime is also rather highly coloured.

Probably the palest is that made with distilled water, but the following resemble the latter very closely: chloride of calcium, sulphate of magnesia, and chloride of magnesium.

## 6. Analyses of the Beers.

(a.) *The Alcohol*.—The percentage of alcohol is highest in No. 4 (sulphate of lime water).

The following shows the specific gravities of the beers with the per cent. of alcohol in each, beginning at the highest—

No.	—	Specific Gravity at 60° F.	Alcohol.
			Per Cent.

(b.) *The Extract or Total Solids*, calculated to grains per gallon, varies from 5.208 grs. per gallon in No. 5 (carbonate of magnesia) water to 2.975 grs. in No. 13, sulphate of potash water.

(c.) *The Nitrogens* were all determined by the Kjeldahl method. The highest results are Nos. 4 and 11, viz., gypsum and imitation Burton waters, each of the beers from these waters contains 0.112 per cent. of nitrogen, thus establishing what has been the general opinion, though denied by certain authorities, e.g., Southby, County Brewers Gazette, 1879, that gypseous waters have an appreciable effect on the solubility of the nitrogenous matter of malt.

\* Became cloudy on standing longer.

The lowest percentage of nitrogen in any of the beers is that made from water containing carbonate of soda (No. 9).

I regret that, owing to clogging of the filters, there was not sufficient beer produced from the carbonate of magnesia water to permit of the nitrogen being estimated, or of the gravity being taken.

No attempt whatever was made to determine in what condition the nitrogen exists in the beers, that is, what proportion of the nitrogen is combined, as albumenoids, peptones, or amides, &c., the subject is an exceedingly complicated one, and it appears there is no reliable method for the separation of these nitrogenous bodies.

(d.) *The Phosphoric Acid* ( $P_2O_5$ ).—The highest percentage of phosphoric acid was found in the beer from distilled water, where it reached 0.122 per cent. by weight, the next was from nitrate of potash water, 0.118 per cent.; then sulphate of magnesia, 0.113 per cent., and sulphate of lime, 0.107 per cent.

(e.) *The Acidity calculated to Lactic Acid*.—The least acid of the beers is No. 5 (carbonate of magnesia) water containing 0.051 per cent. of acidity, the next is No. 9 (carbonate of soda) water 0.072 per cent., Nos. 7 (sulphate of magnesia) and 11 (imitation Burton) are both 0.123 per cent.; five others contain acid equivalent to 0.144 per cent. lactic, while the most acid of all is No. 1 distilled water, which contains 0.18 per cent.

#### 7. The Condition, Flavour, Odour, and Stability of the Beers, and Effect of Waters generally.

In regard to the flavour and odour I have been much assisted by practical brewers. The following is their opinion:—

1. *Distilled Water*.—Gave a thin, soft, clean-flavour beer of no character, odour pleasant.

2. *Carbonate of Lime Water*.—Very bitter and yeasty flavour, odour heavier than 1, harsh after-flavour.

3. *Chloride of Calcium Water*.—Full flavour, sweet pleasant odour.

4. *Sulphate of Lime Water*.—Clean tasted beer.

5. *Carbonate of Magnesia*.—(Not tasted).

6. *Chloride of Magnesium*.—Peculiar, heavy, rather unpleasant flavour.

7. *Sulphate of Magnesia*.—Medicinal flavour, but pleasant smell.

8. *Common Salt*.—Smell bad, taste unpleasant, beer very turbid.

9. *Carbonate of Soda*.—Very worty, soft unpleasant taste.

10. *Nitrate of Potash*.—Heavy smell, unpleasant taste, resembles that from common salt.

11. *Imitation Burton*.—Good, full flavoured, clean-tasted beer.

12. *Edinburgh Gravitation Water*.—Thin unpleasant flavour.

*Sulphate of Potash Water*.—Only fairly good, has a clean thin flavour.

Of the stability of the beers we are of course not yet in a position to offer any opinion.

The limits of this paper made it impossible to carry out further and fuller analytical details than have been attempted. The first intention was to estimate the maltose and dextrin, and the other constituents both of the unboiled and boiled worts, but to have done so would have taken us far into the night and trespassed on your patience already sufficiently drawn upon. Perhaps some other member may feel disposed to continue the investigations, and if such can be found I would suggest besides the greater analytical details, further trials should be made with peaty waters, waters containing iron, and, lastly, with various combinations of salts.

#### 8. The Weights of the Residues.

I regret to say that it cannot be affirmed that the weights of the dried draffs contained in the bottles on the table are strictly accurate. Unfortunately we were only provided with one set of filtering bags, which were used first for filtering the mash, and, after emptying out and washing, were

used to filter from the hops. It was not possible in the limited time between two filtrations and with so many processes all going on simultaneously to remove the last portions of the washed draff adhering to the bags, but which could have been readily detached when dry.

The weights of the dried hops, however, are reliable. It will be observed that both the sulphate of lime water and the imitation Burton water dissolve out less of the extractive matter of the hops than any of the other waters, confirming what is, I believe, well understood by brewers generally.

It is perhaps right to mention here, that when these experiments were first contemplated, application was made to the Inland Revenue Authorities at Somerset House for permission to proceed, and that whenever the object was explained, the permit, which I have here, was courteously sent me.

In conclusion, I have to thank Messrs. Jeffrey and Co., Brewers, Edinburgh, for kindly supplying the raw materials, and for their assistance generally, in the conduct of the experiments; also to our assistant Mr. G. H. Gemmell, F.C.S., for his useful and ready help; and finally to the Council of the University of Edinburgh, for kindly lending the chemical class room for this meeting of the Society.

#### A USEFUL ELECTRIC FURNACE FOR LABORATORY WORK.

EXHIBITED BY J. B. READMAN, D.S.C., F.R.S.E.

The small model furnace placed before you is likely to prove of much use to chemists who have the electric current at hand, and who are making investigations which require very high temperatures. I may say that my experience of the little furnace is somewhat limited, still I have worked it satisfactorily several times. I have observed that there is a tendency in the outer casing (brass) to become overheated, to the injury of the adjusting screws. These difficulties might be due to higher currents than the carbon electrodes were suited to, or to my want of skill in handling the apparatus.

#### DISCUSSION.

The CHAIRMAN in inviting discussion, said Mr. Readman had given assurance that his paper would be commented upon.

Mr. FORD said that Dr. Readman confirmed the general opinion regarding the effect of sulphate of lime.

Mr. G. BEILBY asked if Mr. Readman could tell them whether the small scale laboratory experiments were corroborated by large scale workings.

Mr. FORD referring to Mr. Beilby's remarks, said he had never found it possible to get a good tasting beer in the laboratory. The beer as a rule retained a yeasty flavour, and the clarification was always rather imperfect. The stability of beer depended greatly upon the purity of the yeast.

Dr. MARSHALL said it was difficult to judge from Dr. Readman's experiments what the actual results in brewing would be, because, in nearly every case, Dr. Readman used solutions of single salts. Calcium in combination with different acid radicles gave widely different results, while similar acid radicles in combination with different bases produced very different reactions, e.g., chloride of calcium and chloride of soda had different actions. A mixture of salts would have given a better idea of the actual results in brewing. Two salts of one metal had, as they knew, a different action to that of corresponding salts of different metals. Take the case of sulphate of soda and of chloride of calcium, how would they behave? They did not know that yet. These experiments Dr. Readman had given were merely preliminary. The chief interest would be when the dissolved salts were mixed in definite quantities. In such a case they would deal with results similar to those which were obtained in brewing.

Dr. FAIXONER KING asked whether the various salts acted as solvents upon the matter of the raw material, or if they acted principally by influencing the chemical changes which took place afterwards. They knew, of course, that distillers wanted as soft a water as possible, while on the other hand, brewers wanted a hard water. He wished to know if sulphate of lime acted merely as a limited solvent, or whether its action was due to induced chemical changes. Dr. Readman had told them that soft water, e.g., water containing carbonate of soda, was not a water from which good beer could be made. That raised the question—did the carbonate of soda acted prejudicially by its extractive powers?

Mr. STANFORD (PRESIDENT OF THE SOCIETY) said the experiments had shown that with distilled water the palest colour was obtained. Was it not generally understood that the use of lime salts produced a paler colour? He understood that carbonate of soda produced a dark solution, and he enquired whether the carbonate of soda did not produce any marked effect upon the fermentation on account of its solvent action.

Mr. PETER BOY considered that one special salt was the chief factor in a water used for brewing. Apparently Dr. Readman's experiments showed that sulphate of lime was the salt of most value. As he apprehended the Burton water contained a large quantity of calcium sulphate. He should expect that with carbonate of soda water a larger quantity of extractive matter would be taken out of the malt than with any of the others, and probably a similar result would be obtained, though only to a smaller extent, with carbonate of magnesium. It seemed that the nitrate of potash water had given the least percentage of alcohol. That was what he would naturally expect. The antiseptic action of nitrate of potash would retard the action of the yeast to a greater degree than would any of the other salts. When extracting such a substance as malt, water containing any dissolved salt invariably had a tendency to darken the resulting product.

Dr. JOHN CLARK said that as a preliminary to further investigation, the best method was to experiment as Dr. Readman had done; to examine individually the different effects of various salts. The better to grasp the effect of these individual salts, Dr. Readman had exaggerated the quantities that would naturally occur in water. They could not judge of the taste of beer when it was made on so small a scale for various reasons, more especially on account of the yeast. One could not expect to get such good results in small quantities as in large, e.g., in clarification the results varied greatly. It might be quite true that if one mixed various ingredients in different proportions, one might have totally different results, but the results of Dr. Readman's various experiments were useful in that they showed what effects might be expected, when exaggerated quantities of these different ingredients were present. When Dr. Readman pointed out the influence of exaggerated quantities, he brought out interesting facts; facts which would lead to investigations of the effect of mixed salts such as approached more closely to those found in the actual practice of brewing.

Dr. READMAN, in replying to the discussion, explained that he had found the yeasty flavour very difficult to get rid of, but in some of the beers, especially where sulphate of lime was present, and where imitation Burton water was used, the yeasty flavour practically disappeared. It was very difficult to carry out small experiments in brewing and be, at the same time, consistent with large scale workings, but the results were at all events suggestive, and he thought that to a certain extent large scale experiments would bear out the results of the small set. The experiments showed that in the case of sulphate of lime and the imitation Burton water, there was less extractive matter taken out of the hops than in any of the others. It was curious how much more difficult carbonate of magnesium water was to work than carbonate of soda water. It was really not possible in the limits of one paper to go beyond single salts. Mixed saline constituents he hoped might form the subject of a paper in the future.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*The Dervaux Feed-Water Purifier.* J. C. A. Simon  
Thomas. Zeits. ang. Chem. 1893, 535—536.

THE author refers to Dr. Jones' paper on purifying feed water (Zeits. ang. Chem. 1892, 474), which gives preference to those methods in which the water is treated before it is fed into the boiler. He agrees with this opinion, and states that a further objection to purifying the water in the boiler itself is that the dense purifying solution used does not mix readily with the water in the boiler, and does not therefore attain its object at once. This renders it impossible to make trustworthy tests to determine what quantity of purifying solution is to be added day by day. He then describes at length his experiments with a Dervaux purifying apparatus at the Maiden Powder Factory (Holland) which led him to form the opinion above mentioned. Working for 39 days, according to the instructions supplied by the makers of the apparatus, he arrived at the enormous quantity of 8.5 kilos. of caustic soda and 7.5 kilos. of carbonate of soda as the amount required. On the 40th day the tests showed that too much had been added. The daily quantity was then gradually reduced and finally omitted altogether. He was surprised to find that the makers' tests continued to show, for six days after the additions had entirely ceased, that too much purifying solution, and sufficient for nine days, had been added daily. A second trial was made, which confirmed the first. A table of results is given, which shows that the alkalinity of the water increased constantly, although the amount of cleaning solution added had been daily decreased. The author concludes by saying that in view of this experience he does not hesitate to condemn the purifying of feed water in the boiler itself.—R. B. P.

# PATENTS.

*An Improved Process for Separating Impurities from Water Introduced into a Boiler and Apparatus therefor.* D. H. Lyon, London. Eng. Pat. 2547, February 4, 1893.

THE invention has reference to an improvement in the means described in Eng. Pat. 5036 of 1882 for purifying the feed water to boilers. In the improved arrangement a thin stream of water is fed into the top of the boiler, through a spring check-valve, which stream is immediately vaporised by the surrounding steam, leaving the contained impurities free to fall into a flipped conical basin, placed vertically below the valve and above the water line. The basin communicates with the external atmosphere by means of a branch pipe closed by a cock, so that the collected impurities can be blown out of the boiler at suitable intervals.—E. G. C.

*Improvements in Filters used in the Manufacture of Alcohols, Oils, Greases, and other Matters.* N. Iseli, Chaux-de-Fonds, Switzerland. Eng. Pat. 2896, February 9, 1893.

THE filter described contains a chamber having within it a thick layer of a special filtering medium, which lies between two perforated plates, with a layer of asbestos on its upper side. The liquid to be filtered is passed upwards under pressure through the filtering medium, suitable cocks being provided. The layer of filtering medium can be compressed by means of a pressure screw. The medium consists of ligneous material, which is impregnated with a concentrated solution of magnesium sulphate or chloride, and then mixed with an amount of alkali equivalent to the magnesium salt used. The intimate mixture is dried and carbonised at a white heat and is introduced into the apparatus in a moist state.—J. G. W.

*Improvements in Apparatus applicable for Evaporating Liquids or Saccharine Solutions.* J. A. Morrell and J. Fromherz, both of New Orleans, U.S.A. Eng. Pat. 3170, February 13, 1893.

THE apparatus consists of a metal shell provided with tubes arranged longitudinally between two transverse diaphragms; these tubes have central cores, so that the liquid passing through the tubes assumes an annular form, thus placing the liquid or saccharine solution near the outer periphery of the pipe to facilitate evaporation. The shell is provided with ports for the admission of steam and the liquid is first led through a worm heated by exhaust steam, to bring it up to a suitable temperature; it is then forced through the evaporating tubes of the shell, where it meets with a stream of nitrogenous vapour, surcharged with electricity. This combined action facilitates evaporation, and the resulting vapour is led off in any suitable direction. The electrified nitrogenous vapour is produced by passing air through a red hot chamber containing scrap copper, and then forcing the vapour through an iron pipe containing a copper coil through which a current is flowing.—E. G. C.

*Improvements in Apparatus for Dyeing and Washing Yarn in the Hank.* J. Rhodes, J. Rhodes, jun., and A. B. Perkins, Bradford, Yorks. Eng. Pat. 5291, March 11, 1893.

See under VI., page 390.

*Improved Apparatus for Filtering and Purifying Water.* E. Winkler, Vienna, Austria. Eng. Pat. 5619, March 15, 1893.

THE patent applies to apparatus containing sand, for the filtration of impure water. Preferably, two vessels are employed, of similar construction, and the improvements are principally involved in the arrangement of pipes and valves for regulating and changing the flow of the water through the vessels, as well as for the injection of chemical reagents.—B.

*Plates for Oil- and other Presses.* W. C. Leechman, Colombo, Ceylon. Eng. Pat. 7039, April 6, 1893.

THE invention has reference to improvements in the plates for oil presses described in Eng. Pat. 9526 of 1890 (this Journal, 1891, 708), in which a compound plate was formed consisting of a thick plate with comparatively large holes, overlaid by a thin plate with very fine holes concentric with those below. The construction is now simplified by making the two plates in one piece, and by drilling or punching holes nearly through the plate, and afterwards piercing fine holes through the diaphragm pieces remaining.—E. G. C.

*Improvement in Apparatus for Filtering Liquids or for Separating Liquids from, or Drying, Crystallised or other Granular Matters.* J. Drummond, Govan, N.B. Eng. Pat. 7525, April 13, 1893.

IN this invention a rotary disc or table is provided, with a number of cavities disposed around the common centre, and sliding over a fixed bottom plate. The cavities pass successively under the mouth of a hopper, where they are filled, thence under the mouth of a pipe in communication with a reservoir of compressed air, at the same time that the bottom plate at that place exposes a perforated surface, allowing the liquid to be driven through. As the motion of the table continues the dry granulated matter is either allowed to escape through an open portion of the bottom plate, or it may be retained for further treatment. The movement of the table is intermittent, and the same first motion shaft also regulates the tap for the admission of compressed air, steam, or liquid.—B.

*Improvements in Dyeing Apparatus.* E. Gessler, Metzingeo, Germany. Eng. Pat. 7841, April 18, 1893.

See under VI., page 390.

*Improvements in Pumps for Pumping or Compressing Gases or Vapours.* T. R. Murray, Glasgow. Eng. Pat. 7912, April 19, 1893.

THE object of the invention is to reduce the clearances at the end of cylinders of pumps employed for the compression of air or gases, and is applicable principally to the lower ends of inverted cylinder compressors, as shown in the illustration.

THE end of the cylinder is bored out below the passages or ducts for the air, and is preferably finished conical, the space being filled with oil. The lower end of the piston being provided with a block fitting into the said space and having a number of vertical holes ending in an annular recess, the oil is driven out into the passages behind the

valves, displacing every particle of gas left therein as the piston descends.

—B.

*Improvements in or connected with Apparatus for Cooling Liquids.* W. H. Webb, Bootle, Lancashire. Eng. Pat. 8125, April 22, 1893.

The apparatus comprises a vertical rectangular box with corrugated sides connected by end plates. The milk or other liquid to be cooled is distributed by means of a hopper at the top, and provided with a perforated double conical bottom. The liquid falling down over the upper halves of the corrugated sides is cooled by means of water circulating inside the casing. The lower half of the box is provided with a battery of coils, through which expanded ammonia is forced, the space between the pipes and the corrugated surfaces being filled with brine, kept in circulation by means of a pump or motor. The milk falling over these surfaces is thereby considerably cooled, and is afterwards collected by any suitable arrangement. In cold weather the cooling by ammonia may be dispensed with and the operation conducted with water alone.—E. G. C.

*A New and Improved Method of Connecting Joints in Sanitary Earthenware and other Articles.* A. and F. G. Johnson, Hailey, Staffordshire. Eng. Pat. 9765, May 16, 1893.

The pipes are of the spigot and socket type, lipped at their extremities, and the joint is made by means of an annular elastic packing of round or nearly round section compressed in between the spigot or nozzle and the socket. The spigot may be corrugated to prevent the packing ring from slipping out of place. This form of joint allows considerable play, which is of great advantage in sanitary work.

—E. G. C.

*Improvements in or connected with the Rolls of Machinery for Mixing and Calendering India-rubber or other Materials.* A. G. Brookes, London. From J. E. Davis, Lynn, Mass., U.S.A. Eng. Pat. 21,095, November 7, 1893.

The rollers of the machines used in the mixing of india-rubber compounds and in other operations involving chendering, rapidly become so hot when at work through friction that it is often necessary to stop the machinery for some time to allow them to cool. To obviate this, they have been cast with hollow spindles, so that water could be circulated through them, but owing to their large diameter (14 in.—16 in.) this device is not satisfactory. The inventor now proposes to cast them with a series of longitudinal passages placed close to the circumference of the

roller, fed with water from the ordinary central channel, or alternatively he arranges the circumferential passages in a helical direction.—F. H. L.

*Improvements in the Construction of Filtering Apparatus.* S. Allen, London. Eng. Pat. 23,210, December 2, 1893.

The filter is produced by pouring paper pulp over a perforated disc placed near the bottom of a vessel. After allowing the fibres to settle, the block is covered with another disc of textile material so as to prevent disturbance.—B.

*Process and Apparatus for Cleansing Filtering Material.* H. Reiser, Cologne, Germany. Eng. Pat. 24,526, December 20, 1893.

This invention applies to sand filters, the cleansing, by reversing the current of water, being assisted by air being blown under the perforated plate which supports the sand, in order to cause movement and agitation of the particles, thereby enabling the impurities to be more easily carried away.—B.

*Improvements in the Method of and Apparatus for Determining the Density of Gases.* G. Frères and M. Meslans, both of Paris, France. Eng. Pat. 70, January 1, 1894.

The method and apparatus are sufficiently described in this Journal, 1894, 64. It is claimed for the apparatus that "it indicates the density and the composition of gases in a continuous manner, and at each moment of production." The apparatus is also said to permit, in the special case of combustion and by means of the method, of the regulation of this combustion and of the admission of air to the furnaces of steam boilers, furnaces, &c. It can also, it is stated, be easily arranged so as to act in a mine containing fiery gases.—E. G. C.

## II.—FUEL, GAS, AND LIGHT.

*Processes for Manufacturing Gas from Oil, with Special Reference to the Peebles Process.* W. Ivion Macadam. Abstract of lecture delivered before the North of Ireland Association of Gas Managers, August 1893.

THE Peebles process essentially differs from any of the other oil-gas processes; for, whilst these involve one direct heat action, the Peebles process, by means of a lower heat and constant return circulation of the condensable products, only gives a partial breaking up at each circulation. In the newer forms of apparatus, as at Galashiels, the coal-gas and oil-gas retorts are back to back, and the waste heat of the former serves to heat the latter. The retorts need not, however, be so placed, for at Peebles the coal-gas and oil-gas are made in the same oven, but for economical working the Galashiels setting should be best. The coal-gas retorts are of the usual  $\Omega$ -shape and size, and set in the ordinary way, whilst the best form of retort for the oil-gas is cylindrical. The Galashiels retorts are 8 ft. long and 27 in. internal bore, and they are laid with a backward inclination. From the front of the retort there is an ordinary ascension, bridge, and dip-pipe to the hydraulic main. The condensers are nearly horizontal, with a slight upward tendency, and lead to a scrubber on the principle adopted regularly in shale-oil works. The trays in the scrubber are fed with oil from a cistern attached to the upper part of the apparatus. From the scrubber the gas passes to the ordinary dry purifiers, where it meets with the coal-gas, and the mixed gases then go to the holder in the usual manner. The oil to the retort is obtained from what is called the compensating tank. In this tank the overflow from the hydraulic main, the liquids from the condensers, and the fresh oil are intermingled, with the result that a perfectly liquid substance is maintained throughout the whole working. Moreover, the apparatus, being of considerable

size, acts as a settling-tank, in which any solid carbonaceous matter is removed. The oil passes from the compensating tank by means of a pipe with regulating valve to the ascension pipe, where the introduction of the liquid oil tends to wash the ascending gas and remove any suspended carbonaceous particles. By this circulation method liquid residuals are avoided, and the residue left in the retort, when it is coked down, is a dense and very pure carbon with less than 0.5 per cent. of ash and readily burned. For this solid residue 20s. per ton has been regularly obtained at Peebles. It yields a smokeless flame of great heat intensity. The gas yielded by this method runs with "blue" oils about 85 to 86 cubic feet per gallon, and the illuminating value when the gas is burned by itself is about 59-candle power. When burned in admixture with poorer illuminating gas the value is much greater. A month's actual working yielded—

Coal-gas .....	1,217,000 cubic feet of 18-candle power.
Oil-gas .....	253,400 "
Total gases ....	1,671,000 " 30.71 "
	Cubic Feet. Candles.
Coal-gas...	$1,217,000 \div 5 = 243,500 \times 18 = 4,383,360$
Total gas...	$1,671,000 \div 5 = 334,200 \times 30.71 = 8,976,013$

Therefore candle power from 253,400 cubic feet of oil-gas is 4,592,682 candles, which, divided by the make (253,400 cubic feet) = 18.12 candles per cubic foot, and  $\times 5 = 90.60$  candle power as the true illuminating value of the oil-gas as an enricher. This gain in illuminating value by mixing is equal to 53.74 per cent. To explain this gain we need to consider several points. If in the gas flame the heat, in this case derived from the burning of the hydrogen, carbon monoxide, &c., be sufficient to produce a great enough temperature the maximum of light will result. If these gases are too small in amount then the flame becomes smoky and the light less. In oil-gas the last condition holds good, and the balance is brought about by the admixture with a poorly carbonaceous gas containing much hydrogen, and which on burning gives sufficient heat to render the excess carbon of the oil-gas incandescent. In other words, the excess of carbon in the oil-gas is rendered incandescent by the excess of heat-producing bodies in the poorer gas, and the result is an excess of light over that obtained from either gas alone.

*Conditions for the Production of Generator Gas observed during Combustion of Carbon in Air.* R. Ernst. J. Prakt. Chem. 49, 31—45.

COKE was coarsely powdered, freed from dust by sifting, and heated to a very high temperature in a hessian crucible to remove hydrocarbons. The material thus obtained was burnt in a current of air passing through a porcelain tube heated in an ordinary combustion furnace. The temperature of the tube was ascertained by means of Le Chatelier's thermo-electric pyrometer. The gases formed during the passage of the air over the coke, were absorbed and determined.

The length of the layer of coke, the rate of passage of the air, and the temperature, were independently varied in the experiments. It was found that the composition of the gaseous products of combustion depend almost entirely on the temperature. The formation of carbonic oxide and carbonic anhydride begins at about 100° C., the production of the latter increasing rapidly up to 700°, when it forms about 20 per cent. of the gases collected. The amount of carbonic oxide at this temperature is still small, being only about 3 per cent. As the temperature continues to rise, however, the carbonic oxide increases in amount at the expense of the carbonic anhydride, and at 1,000° it forms one third of the gases, the remainder being nitrogen from the air. It was shown that at this temperature carbonic oxide is the direct product of the combustion, for carbonic anhydride could not be entirely reduced to carbonic oxide under similar conditions of experiment.

Since carbonic oxide is the only oxidation product at 1,000°, generator gas should be made at about that temperature. If high temperatures are desired, the carbon should

not be supplied with all the air necessary for its complete combustion, but only with that proportion sufficient to form carbonic oxide, which should then be burnt with a further supply of air.

The experiments explain why carbon burns at a moderate heat (730° C.) without a flame, but at a brighter heat (1,000°) with a flame.—J. W.

*Valuation of Fuels.* F. Fischer. Zeits. ang. Chem. 1893, 677.

See under XXIII., page 420.

## PATENTS.

*Improvements in Horizontal Coke Ovens.* F. Brunck, Dortmund, Germany. Eng. Pat. 4475, March 1, 1893.

This invention relates to the arrangement of the heating channels or flues in horizontal coke ovens with vertical wall-heating channel systems.

In ordinary coke ovens of this kind, constructed for recovering by products, the upper part of the charge receives less heat than the lower, with the result that the coking period is longer, and the quality of the coke inferior in the upper part.

The improvements consist in the arrangement of the upper horizontal channels connecting the vertical flues in ovens with double vertical-heating flues, and in horizontal ovens, with single or double vertical-heating flues, in making the walls of the oven chambers and vertical flues of varying thickness so as to equalise the heating effect. Details are given of the arrangement of the flues, &c.—B. B. P.

*A Process for the Manufacture of Oil-Gas.* J. Moeller, London. Eng. Pat. 8510, April 27, 1893.

This invention relates to the manufacture of oil-gas from ordinary petroleum, shale-oil, or other oil, or any fatty substance that can be melted. A vessel is charged to a high pressure with some combustible gas, which is used for operating an injector for forcing the oil, or melted fat, into a highly heated retort. The retort is partially filled with some porous refractory material. The spray of oil is directed into one end of the retort, and, passing over and through the porous refractory material, becomes converted into gas.—R. B. P.

*Improvements in Washers for the Extraction of Tar, Ammonia, Carbonic Acid, and Sulphuretted Hydrogen, from Coal-Gas.* F. S. Cripps, Sutton, Surrey. Eng. Pat. 14,783, August 2, 1893.

FIG. 1 shows a vertical section, and FIG. 2 a plan, with the top plate removed, of the washer. A is a horizontal plate with annular rings B east on its lower side; to these are attached rings C of thin sheet iron with their lower edges serrated, the form of which is shown by FIG. 3. A distributing box D projects inwards towards the centre. It has openings E on both sides, which communicate with the annular spaces formed by the rings on A. In A are openings F. When working, the washer is filled with liquor until the edges of the rings C are sealed, the level being regulated by the overflow valve J. Gas entering at H is distributed by the box D into the annular spaces L. It depresses the liquor in them and forces its way out past the serrated edges C, issuing in streams of fine bubbles, and is thus brought into intimate contact with the washing liquor. It then passes up through the openings F into the gas space above A, and out at I. Tar collecting in the lower part of the washer is continuously withdrawn through the overflow K. This consists of two concentric tubes, the outer one of which is fixed, and communicates at its lower

end with the bottom of the washer, where the tar collects, and at its upper end with the gas space above A. The inner tube is adjustable in height. The tar enters and rises

Fig. 1.

Fig. 2.

Fig. 3.

up the outer tube until it reaches the top edge of the inner one, into which it flows, and runs out through the siphon attached to its lower end.—R. B. P.

*Improvements in or relating to the Vaporisation of Petroleum and other Liquids.* A. J. Boulton, London. From S. C. Penchen and P. Clarke, both of Toronto, Canada. Eng. Pat. 340, January 6, 1894.

These inventors propose to vaporise liquids by means of heat generated electrically in two carbon plates. The liquid is contained in a closed vessel, and the carbon plates suspended in it from a float. In place of the carbon plates, wire resistance coils may be used.—R. B. P.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*Note on Stearin Pitch.* E. Donath and R. Strasser. Chem. Zeit. 17, 1788.

In the distillation of the fatty acids used in the manufacture of candles, from 2 up to 7 per cent. of a tarry residue remains behind in the still, which on redistillation with superheated steam at 300° C. leaves a residue of stearin pitch in the form of a black, asphaltic mass, amounting to from 2 to 3 per cent. of the original fatty acids. At present this stearin pitch is used at Ronbaix for the production of oil gas. About 21·6 per cent. of the pitch is soluble in absolute alcohol, forming a fluorescent and faintly acid solution. Of saponifiable matter about 9 per cent. is present. On distillation in a spacious retort about 80·5 per cent. distils off, about 19·5 per cent. of solid, carbonaceous matter remaining behind. On distilling the distillate the following fractions were obtained:—

	Per Cent.
1. From 50° to 150° C. ....	10·3
2. From 150° to 200° C. ....	8·8
3. From 200° to 250° C. ....	10·0
4. From 250° to 300° C. ....	15·0
5. From 300° to 350° C. ....	25·9
6. Above 350° C. ....	29·2

The first fraction contains acrolein, the other fractions, the specific gravity of which varies from 0·7861 to 0·8877, are of yellowish-brown colour and are all strongly fluorescent. Fractions 5 and 6 have an average specific viscosity (water = 100) of 3·26, and at temperatures below 10° C. considerable quantities of hydrocarbons of the nature of vaseline separate from them. These two fractions, which represent 55 per cent. of the total distillate, are doubtless suited for use as lubricants, and the stearin pitch itself, preferably after saponification of the free fatty acids, may be found useful for thickening of lubricants. The formation and composition of stearin pitch is of interest with regard to the formation of petroleum, inasmuch as it furnishes some additional support for Engler and Höfer's theory of the formation of petroleum from fatty acids.

—C. O. W.

*The Carbonisation of Wood.* J. Sartig. Chem. Zeit. 17, 1269.

RELIABLE data on the yield of products resulting from the destructive distillation of various kinds of wood on a large scale are scarcely to be found in chemical literature. (See E. T. Chapman, Chem. News, 1871, 91—93, and Watson Smith, J. Chem. Soc. 1871, 1101—1108; also Muspratt's and Spon's Dictionaries, and Ramsay and Chorley, this Journal, 1892, 395 and 872). The author communicates the results obtained in working with upright portable wrought-iron retorts of 12 mm. thickness of plate, a height of 3·1 metres, and a diameter of 1·25 metres. These retorts were charged cold and transferred to the furnace by means of a crane, this method being preferable to the employment of horizontal retorts, on account of the smaller production of charcoal waste.

3,647 kilos. of beech wood (from logs not less than 10 centimetres thick), split into pieces of equal thickness and seasoned for two years, formed the total charge of three retorts working simultaneously. 15 hours' heating to a temperature of about 350° C. completed the distillation. The yields of the single retorts differed from each other, probably in consequence of unequal heating. Thus the quantity of tar and acid amounted to 553·09, 582·65, and 532·70 kilos., that of charcoal to 378, 359, and 385 kilos. respectively. In spite of the varying quantity, the pyroligneous acid was in all cases equally strong, possessing a specific gravity of 1·039 at 15° C. and containing 11·78 per cent. total acid (calculated as acetic acid). The yield of the three retorts taken together was:—

	Kilos.
Pyroligneous acid	1,448·44
Tar	220
Charcoal	1,122 (of which 89 kilos. of dust).

The total consumption of coal (medium quality) amounted to 419 kilos.

The pyroligneous acid was found to contain 2·946 per cent. of absolute wood-spirit. The tar had a specific gravity of 1·080, and yielded, on distillation from an ordinary cast-iron still, per 100 kilos.:—

	Kilos.
1. Crude wood acid	20·1 (giving 0·656 kilo. absolute wood-spirit and 2·94 kilos. calcium acetate).
2. Light tar oil	5·1 (sp. gr. 0·970).
3. Heavy oil	12·0 ( " 1·043).
4. Pitch	61·0
5. Gases	1·5 (by difference).

A charge of birch wood (cut only one month previously), freed from bark and weighing 3,209 kilos., produced 1,731 kilos. of acetic acid, sp. gr. 1·010 (11·82 per cent. acid), containing 1·5 per cent. absolute wood-spirit (laboratory determination only), and 177 kilos. tar, sp. gr. 1·078. The yield of tar and charcoal shows no material difference on comparison with that obtained from beech wood, while the yield of acetic acid is somewhat better, and that of wood-spirit smaller. Products from birch wood (the charcoal more especially) fetching a better price in the market, a preference should be given to this wood wherever its cost, inclusive of the expense of the removal of the bark, does not exceed that of beech wood.—F. M.

*The Distinction of Birch- from Pine Tar.* E. Hirschsohn. Pharm. Zeits. Russl. 1893, **32**, 657.

## PATENT.

*Improvements relating to the Distillation and Breaking-up of Liquid Hydrocarbons and similar Substances, and to Apparatus therefor.* F. W. Clark, South Norwood Hill, Surrey. Eng. Pat. 4510, March 1, 1893.

This invention relates to the distillation or breaking up of liquid hydrocarbons and to the separation and recovery of the resulting products, "the distillation and breaking up" being effected by a method "in which air or other gas is passed over the liquid in an evaporator or retort."

The process consists essentially in introducing the liquid in thin streams into suitable evaporators, in which the more volatile parts are driven off by heat, or by reducing the pressure, or by both together. The vapours are then forced into a cooler by aid of a "carrier," such as air, and are there subjected to cold, or an increase of pressure, or both together, which causes them to condense. By varying the temperatures and pressures in the evaporator and cooler, products of higher or lower specific gravity can be obtained at will.

The evaporator consists of a closed cylinder slightly inclined from the horizontal. Two tube-plates, one near each end of the cylinder, divide it into three compartments. The front compartment is divided into halves by a horizontal plate. Between the two tube plates run a number of tubes parallel to the axis of the cylinder, which connect the two end compartments. In the front compartment the division plate divides the tubes into two sets, an upper and a lower one.

Into the lower set the liquid to be evaporated is admitted and its more volatile components driven off as it passes along them, by heat, which is applied to the exterior of the tubes by admitting hot air, water, or steam to the central compartment, through which the tubes pass. At the same time the air, or other carrying medium, which is admitted to the lower half of the front compartment, passes along the lower set of tubes to the back compartment and returns to the upper half of the front one along the upper set of tubes, carrying with it any vapour driven off from the liquid under treatment. This vapour and the "carrying" medium are then forced into the cooler by any suitable means. The cooler is similar in construction to the evaporator, only in it, instead of being subjected to heat and a diminished pressure, the vapours are subjected to cold and an increase of pressure, which causes them to condense.—R. B. P.

## IV.—COLOURING MATTERS AND DYES.

*Chrysin.* G. Darier. Ber. **27**, 21—22.

RÉCARD discovered a yellow colouring matter in the buds of the poplar, termed chrysin,  $C_{15}H_{10}O_4$ , which Graebe believed to have a constitution similar to that of euxanthone. The author succeeded in getting a yield of 2·5 to 3 grms. of chrysin from 1,000 grms. of the poplar buds.

Evidence was obtained, through the formation of a di-acetyldinitrochrysin, of the presence of two hydroxyl groups in chrysin, such as have been shown to be present in euxanthone; also the general similarity of the two bodies lends further support to the belief of the presence in both of a pyrone ring—

Euxanthone is derived by the action of heat or of sulphuric acid on euxanthic acid, the magnesium salt of which is the chief constituent of the well-known water-colour pigment *Indian yellow*.—W. S.

*Salicylic Acid Azo Colouring Matters. A Study on the Influence of Constitution on Fastness.* M. D. Bona. Farb. Zeit. **5**, 120—121.

THE author arrives at the following conclusions with regard to colouring matters containing salicylic acid:—

(1.) Salicylic acid, by its presence in an azo-dyestuff, influences the shade of that dyestuff in the direction of yellow.

(2.) Salicylic acid tends to increase the fastness to light.

(3.) Owing to the close connection of the carboxy- and hydroxy-group; in salicylic acid, it yields dyestuffs which are generally fast to alkalis. But this is not the case if some component sensitive to alkalis is closely combined with the salicylic acid. The behaviour of resorcinol needs further explanation.

(4.) Salicylic acid yields colouring matters which are fast to acids, unless some basic group is present in the molecule.

(5.) No dyestuff containing salicylic acid appears to be fast to chlorine.—R. B. P.

*See under VI., page 388.*

*The Constitution of the Colouring Matters of the Magenta Group.* Prud'homme and C. Rabaut. Bull. Soc. Ind. Mulhouse, 1893, 272—277.

For some years Rosenstiel has advocated the theory that the colouring matters of the magenta group are in reality the ethers of aromatic amido alcohols, and that the formula, for instance, of para-magenta instead of being written—

should be  $(C_6H_4.NH_2)_3.C.Cl$ , i.e., that the chlorine is directly united to the central carbon atom. To throw light on this question the authors have made researches as to the influence of ammonia and other agencies on these colouring matters.

**Action of Gaseous Ammonia on Magenta.**—When ammonia is passed in the cold over dry finely-powdered magenta (rosaniline hydrochloride), the green metallic crystals change to a violet powder, which finally becomes red. The violet powder corresponds to the absorption of one molecule of ammonia, the red to two molecules. On heating the new compound ammonia is liberated and magenta regenerated. The ammonia is also liberated *in vacuo* in the cold. If magenta were the hydrochloride of a secondary amine, as the older formula would indicate, it would form with ammonia, ammonium chloride and—

but this reaction does not take place.

**Decomposition of the Chlorides and Iodides of Amines by Ammonia.**—To show more conclusively that the effect of ammonia on the hydrochloride of an amine would be the production of the amine and ammonium chloride, experiments were made with haloid salts of various primary and secondary amines, the result being invariably that indicated. The salts of tertiary amines are without interest, being very unstable and readily decomposed by water.

*Compounds formed by Ammonia and the Colouring Matters of the Magenta Group.*—Rosaniline sulphate absorbs ammonia less readily than the hydrochloride; under its influence, however, it takes up two ammonia molecules, becoming brownish-black and finally dark red. The oxalate exhibits similar changes. Rosaniline violet (hexamethylosaniline) becomes indigo blue, and with two ammonia molecules violet-grey. Malachite green (oxalate) contains an excess of oxalic acid, and the ammonia first combines with this and then with the colouring matter to form a reddish-grey product. The increase of weight when ammonia acts on this dyestuff varies with the amount of free oxalic acid present, and might serve for a method of quantitative estimation of this free acid.

*Action of Sodium Ethylate on Magenta.*—Sodium ethylate completely decolorises magenta in alcoholic solution. If magenta were the hydrochloride of a secondary amine the anhydrous base would be formed, but as this hypothesis has been proved incorrect, the reaction is as follows :—

This ether is so unstable that it is decomposed on adding water, into alcohol and rosaniline, the latter being thrown down as a colourless precipitate, which, on exposure to air, acquires a pink shade.—R. B. B.

## PATENTS.

*Improvement in the Manufacture of Refined Indigo.*  
S. J. Simpkin, Leeds. Eng. Pat. 1113, January 18, 1893.

The crude indigo as imported is treated by any of the known methods for reducing and dissolving the indigo, in a closed jacketed vessel provided with an agitator, and so arranged that the operation can be conducted out of contact with the air, and in the presence of a non-oxidising gas, such as coal gas, nitrogen, hydrogen, or a mixture of any of them. As an example of the method employed, the following details are given. After filling the vessel with gas a mixture of 100 lb. of raw indigo finely ground in water, 200 lb. of ferrous sulphate dissolved in water, and 80 lb. of lime made into a thin sludge, is run through a siphon pipe into the apparatus, thoroughly mixed by means of the agitator, and the vessel is filled with hot water to dissolve the indigo white. The solution is then separated, and the indigo blue precipitated by oxidation. Other reducing agents may be used, and the proportions may be varied. A sectional drawing of the apparatus accompanies the specification.—T. A. L.

*Manufacture of New Colouring Matters by the Action of  
Diazo Compounds on the Hydrazone Derivatives of  
Orallygluetic Ether.* J. H. Ziegler, Bâle, Switzerland.  
Eng. Pat. 5693, March 16, 1893.

THE colours produced according to this patent are ethers of the tartrazines (Eng. Pat. 9858 of 1885; this Journal, 1886, 427). The method employed for their preparation is based upon the observation that the hydrazones of oxalylacetic ether are capable of combining with diazo compounds, the hydrogen of the methylene group being replaced by the hydrazone group, forming an osazone. If the colouring matter, produced as described below, by the interaction of phenylhydrazine sulphonic acid, oxalylacetic ether, and diazobenzene sulphonic acid, be heated with the calculated quantity of caustic soda, it is converted into tartrazine. About 19 kilos. of phenylhydrazine sulphonic acid, 18·8 kilos. of oxalylacetic ether—

and 15 kilos. of crystallised sodium acetate are mixed with 100 litres of water, agitated, and heated to 50° C., when the hydrazone compound is produced—

After cooling, 5 kilos. of sodium carbonate are added and subsequently the diazobenzene sulphonic acid prepared by diazotising 22 kilos. of sodium sulphanilate with 7 kilos. of sodium nitrite and 22 litres of 33 per cent. hydrochloric acid in 100 litres of water. The solution turns an intense yellow, owing to the formation of the oxazine of the ether of dioxystartic acid—

The dyestuff can be separated by adding salt, and, as described above, on heating with caustic soda it can be saponified. The phenylhydrazine sulphonic acid can be replaced by the tolyl-, xyl-, or naphthyl-hydrazines, or their sulphonic or carboxylic acids or their nitro-, hydroxy-, or ethoxy-derivatives, and similarly for the sulphonic acid may be substituted, aniline, the toluidines, the xylinines, the naphthylamines, benzidine, or tolidine, and their sulphonic or carboxylic acids, and nitro- and amido- derivatives, and compounds like amido-azobenzene may also be employed.

—T. A. L.

*The Production or Manufacture of Colouring Matters.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 6035, March 21, 1893.

AN extension of Eng. Pats. 825 and 4757 of 1893 (this Journal, 1894, 31 and 245), which refer to the production of blue mordant colouring matters from  $\beta$ -naphthoquinone sulphonic acid or  $\beta$ -naphthohydroquinone sulphonic acid and the nitroso derivatives of secondary or tertiary amines in presence of thiosulphates, or else from certain sulphonic acids of  $\beta$ -naphthoquinone and alkylated *p*-phenylenediamine thiosulphonic acids. It has now been discovered that it is not necessary to prepare the naphthoquinone or naphthohydroquinone sulphonic acids, but that the nitroso-naphthols and nitrosonaphthol sulphonic acids can be used. For instance, the same dyestuffs are obtained by taking instead of 1-2-4 naphthoquinone sulphonic acid, either 2-1-4-nitrosonaphthol sulphonic acid, or 1-2-nitrosonaphthol, and reacting with them on the condensation products from the nitroso-derivatives of secondary and tertiary amines and thiosulphates. It is supposed that during the reaction the nitroso group is reduced to the amido group, and this is subsequently replaced by oxygen. The following example is an instance of the method employed. A solution of 9.3 kilos. of nitrosodimethylaniline hydrochloride and 18 kilos. of 33 per cent. acetic acid in 300 litres of water, is mixed with 26 kilos. of sodium thiosulphate dissolved in hot water and the mixture is heated until the liquid becomes colourless, when the formation of the dimethyl-*p*-phenylenediamine sulphonic acid is complete; 1.4 kilos. of sodium 1-2-6-nitroso-naphthol sulphonate are then stirred in gradually. The dyestuff begins to form at once and separates in small bronze-coloured crystals. It is filtered off whilst hot and is sufficiently pure for dyeing purposes. The colouring matter is identical with that obtained from nitrosodimethylaniline sodium thiosulphate and  $\beta$ -naphthoquinone 6-sulphonic acid. It probably has the following formula:—

Other nitroso derivatives may be substituted for those mentioned, and in general the dyestuffs claimed are formed by the interaction of the condensation products from the nitroso derivatives of secondary or tertiary aromatic amines or substituted amines and thiosulphates on the nitroso derivatives of the naphthalene series, or on the quinones corresponding to such nitroso derivatives, excepting certain  $\beta$ -naphthoquinone sulphonic acids already described in Eng. Pat. 4757 of 1893 (this Journal, 1894, 245).—T. A. L.

*The Manufacture or Production of Colouring Matters.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 6035A, March 21, 1893.

THIS is an extension of Eng. Pat. 825 of 1893 (this Journal, 1894, 31), according to which blue mordant colouring matters were produced by condensing  $\beta$ -naphtho- or  $\beta$ -naphthohydroquinone sulphonic acid with the nitroso derivatives of secondary or tertiary amines in presence of

thiosulphates. As already described more fully in the preceding specification (see above), these quinones can be replaced by the corresponding nitroso-naphthols, and the colouring matters obtained are identical. A mixture of 9.3 kilos. of nitrosodimethylaniline hydrochloride and 14 kilos. of sodium 1-2-6-nitroso-naphthol sulphonic acid, is dissolved in 300 litres of water mixed with 18 kilos. of 33 per cent. acetic acid, and then with a hot solution of 26 kilos. of sodium thiosulphate in 100 litres of water. The formation of the dyestuff commences immediately and the colouring matter separates in bronzy crystals, which are filtered off whilst hot. The dyestuff is identical with that described in the preceding abstract.—T. A. L.

*The Manufacture or Production of a New Blue Colouring Matter.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 7181, April 7, 1893.

THE blue-violet dye-stuff obtained from nitrosodimethylaniline hydrochloride and gallamine, according to Eng. Pat. 2941 of 1889 (this Journal, 1889, 981), is insoluble in water and has to be treated with sodium bisulphite in order to utilise it for dyeing or printing purposes, when it is known as "*Gallamine Blue*." The present specification describes the preparation of the higher homologue of this substance from nitroso-diethylaniline, and the product obtained has valuable properties. It dissolves easily in water, dyes evenly, and a purer blue than any of the known oxazines. It stands furling equally as well as gallamine blue, is fast to light, and is unaltered by alkalis, dilute acids, or chlorine. It is prepared by heating 1 kilo. of gallamine with 1.5 to 2 kilos. of nitrosodiethylaniline hydrochloride in 1 kilo. of alcohol until a test dissolves in water with a pure blue colour. The melt is then poured into 10 litres of water and a small quantity of hydrochloric acid is added. After a short time the dyestuff separates as a crystalline precipitate. It has the formula—

and is analogous to "*Gallocyanine*."—T. A. L.

*The Manufacture or Production of New Alizarin Dyestuffs.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 7182, April 7, 1893.

THE process consists in methylating or ethylating  $\alpha$ -amido-alizarin and its homologues, such as  $\alpha$ -amido-flavopurpurin,  $\alpha$ -amido-anthrappurpurin, &c., by heating them in presence of alcohol with an alkyl haloid or other alkylating agent to a high temperature under pressure. The alkylated colouring matters produced yield bluer shades with mordants than the non-alkylated products. Thus  $\alpha$ -amido-alizarin gives garnet-red shades on alumina, whereas ethylated  $\alpha$ -amido-alizarin dyes a Bordeaux shade with a strong bluish hue on the same mordant. This product is obtained by heating 10 kilos. of dry  $\alpha$ -amido-alizarin, 10 kilos. of ethyl bromide, and 100 kilos. of ethyl alcohol in an autoclave for five hours to 150° C. The excess of acid is then distilled off and the residue is extracted with dilute soda lye, from which solution, after having been heated to boiling, the dyestuff is precipitated by adding an acid, filtered off and washed to remove acid. It forms a dark violet paste which dissolves in alkalis to a bluish solution and in hot concentrated hydrochloric acid to a yellow solution, from which the hydrochloride partially separates on cooling. Its solution in concentrated sulphuric acid is yellower than that of  $\alpha$ -amido-alizarin.

—T. A. L.

*Manufacture of Colouring Matters.* O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 7185, April 7, 1893.

According to Eng. Pat. 19,820 of 1892 (this Journal, 1893, 922) a red colouring matter is produced by heating rhodamine with *m*-dinitro-chlorobenzene in alcohol. Similar, but yellower, colouring matters are obtained by condensing dinitro-chlorobenzene and *o*- and *p*-nitrobenzyl chlorides with the symmetrical diethyl- or dimethyl-*m* amidophenolphthaleines. The compounds thus obtained are less soluble in alcohol, acetic acid, and water than the corresponding tetra-alkyl colouring matters. They dissolve in 50 percent. acetic acid or in alcohol at the ordinary temperature, and in water on heating. Salt precipitates the colour from the aqueous solution in a flocculent condition, and the dry colouring matter forms a light yellowish-red powder having a green metallic lustre. The two following examples explain the methods employed:—(1.) 21 kilos. of diethyl-*m*-amido-phenolphthaleine hydrochloride, 8.6 kilos. of *p*-nitrobenzyl chloride, and 2.65 kilos. of calcined soda dissolved in 10 kilos. of water are boiled in 50 litres of alcohol for several hours. The alcohol is then distilled off and the colouring matter is dissolved in hot water and after filtration precipitated with salt. (2.) 19.3 kilos. of diethyl-*m*-amido-phenolphthaleine and 10.2 kilos. of dinitro-chlorobenzene are heated in 50 litres of alcohol for several hours, and after distilling off the alcohol the residue is extracted with a large quantity of boiling water containing a little hydrochloric acid. After filtering this solution the dyestuff is precipitated with salt.—T. A. L.

*Manufacture of a Novel Diamido-Base and of Colouring Matters from the same.* O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 7187, April 7, 1893.

THE base referred to is obtained by nitrating benz-*p*-nitranilide, reducing the trinitro-compound obtained, and eliminating water from the triamido derivative. This produces *p*-diamido-phenyl-benzimidazole, which yields a tetrazo compound capable of combining with phenols and their derivatives, giving cotton colouring matters. The successive operations are as follows:—When benz-*p*-nitranilide is dissolved in five times its weight of sulphuric acid monohydrate and nitrated by a mixture of fuming nitric acid and monohydrate, it is converted into *p*-trinitro-benzanilide—

This compound is insoluble in water, alcohol, or ether, but soluble in glacial acetic acid or acetic ether. On reduction with iron and hydrochloric acid it yields triamido-benzanilide—

The triamine is soluble in hot water and crystallises out on cooling. It also dissolves in hot alcohol and acetone. Its salts are easily soluble in cold water. When heated *in vacuo* to 250° C. one molecule of water is split off and the following compound is produced:—

This anhydro base is insoluble in water or ether, soluble in alcohol and acetone, and its melting point is above 250° C. With sodium nitrite and a mineral acid it forms an easily soluble tetrazo compound, which readily combines with phenols, naphthols, their sulphonic and carboxylic acids, and with amido acids. The usual variations may be made in the combinations as with the Congo colouring matters. The colours are fast to soap and acids and the shades produced are brighter and bluer than those from the colouring matters obtained according to Eng. Pat. 10,667 of 1892 (this Journal, 1893, 515).—T. A. L.

*The Manufacture of Blue Colouring Matter containing Sulphur.* W. H. Claus and A. Rée, Droylsden, Manchester. Eng. Pat. 8221, April 24, 1893.

THE following is the preparation of methylene blue according to this specification. About 18 kilos. of dimethyl-aniline are converted into the nitroso derivative, which is filtered off, yielding about 26 kilos. of *p*-nitroso-dimethyl-aniline hydrochloride. This is dissolved in 150 litres of hot water and 120 kilos. of acetic acid (12° Tw.) and heated to 75° C. To this solution is added 75 kilos. of sodium thio-sulphate in 350 litres of water. When the yellow colour of the liquor has disappeared the temperature is raised to 80° C. and 120 kilos. of zinc chloride (102° Tw.), 15 kilos. of dimethyl-aniline, and 17 kilos. of hydrochloric acid (28° Tw.) are added. Immediately afterwards, a solution of 25 kilos. of sodium bichromate and 5 kilos. of sulphuric acid in 250 litres of water is run in, the temperature being raised to 90° C., and the whole being well stirred during the oxidation, which takes about three minutes. The colour, which is formed at once, is filtered off and purified by dissolving it in water and precipitating with salt.—T. A. L.

*Improvements in the Manufacture of a Diamido Base and of Tetrazo Colouring Matters derived therefrom.* W. G. Thompson and J. Moore, Middleton, Lancashire. Eng. Pat. 2232, February 1, 1894.

By heating together tolidine, formaldehyde, and the basic hydrochloride of *m*-tolylene diamine in alcohol on the water-bath for several hours, the next higher homologue of one of the products described in Eng. Pat. 20,301 of 1893 (this Journal, 1894, 32) is obtained. The melt is treated with hot dilute hydrochloric acid, the solution filtered, and the new base precipitated as a brown powder by adding ammonia. The following formula is assigned to it:—

When heated above 100° C. the base becomes viscous. It is not very soluble in alcohol, but the hydrochloride and sulphate are easily soluble in water. It is easily converted into the tetrazo compound, and the colouring matters claimed, which dye unmordanted cotton red, are obtained by combining one molecular proportion of the tetrazo compound with two molecular proportions of naphthionic acid or of 2-3'-naphthylamine sulphonic acid. Both these colouring matters dissolve in concentrated sulphuric acid to a blue solution.—T. A. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Wild Silk.* H. Silbermann. Färb. Zeit. 5, 19—21.

WILD silk is of constantly increasing importance, not only as a substitute for cultivated silk, but also as a fibre capable of definite applications, and for certain purposes unsurpassed. Wild silks are distinguished from cultivated by their chemical composition and morphological structure. In the raw condition they are dull, dark coloured, and consisting of a thick, double fibre. Tussah silk fibre shows longitudinal striations, due partly to fine air-canals within the fibre, and partly to the fact that each single fibre is composed of a number of excessively fine fibrils, easily seen under the microscope in a transverse section. This structure and the thickness of the fibre cause great tenacity. The diameter of wild silk fibre is often 60—70 thousandths of a millimetre, that of the cultivated fibre seldom exceeding 32 thousandths.

While ordinary silk is readily dissolved by a solution of zinc chloride at 15° B., tussah requires a solution at 60° B. It dissolves only with difficulty in ammoniacal solution of copper hydrate, and is less readily attacked by boiling hydrochloric acid than the cultivated product.

Wild silk cocoons are large and rich in silk; certain kinds measure over 120 mm. in length. The price is considerably below that of cultivated silk. Wild silk appears in commerce as a brownish fibre with a somewhat penetrating odour, due probably to a rotting process to which the cocoons are subjected before reeling. Certain kinds of wild silk are capable of being reeled, while others are treated like silk waste, being carded, combed, and spun.

The most important variety is Indian tussah (*Antheraea mylitta*). Several crops of cocoons are obtained in the year, the September crop being best suited for reeling. The cocoon is attached to a twig by a handle-like appendage. It is oval, regular in shape, and evenly spun. Its hardness is due to urate of soda, with which the caterpillar impregnates each layer as completed. The cocoon is 45 to 50 mm. in length, and 25–30 in breadth. When dry it weighs 2–3 grms., and contains 30 per cent. silk fibre. 1 kilo. silk is obtained from 10–15 kilos. of fresh or 3–5 kilos. dried cocoons. The length of the fibre is 1,200–1,400 metres, of which 600–700 metres can be reeled. The diameter varies from 50 to 90 thousandths of a millimetre. The increasing demand for tussah has led to the frequent admixture of this fibre with less valuable wild silks, *eg.*, *Antheraea fruhii*, *Ant. puphia*, *Ant. rivalica*, &c.

Chinese tussah (*Ant. pernyi*) in structure and chemical behaviour greatly resembles Indian tussah. The caterpillar lives upon the Chinese oak, and produces irregularly spun, soft cocoons, 10 mm. long by 25 mm. broad, having a small opening at one end. Reeling in the ordinary manner is impossible, since the cocoons sink in boiling water; they are therefore softened by steam in specially constructed baskets, and then reeled. They contain about 20 per cent. silk fibre. The length of the fibre is 650–700 metres, and its diameter 68 thousandths of a millimetre.

Wild silk is more hygroscopic than cultivated silk. The amount of moisture contained exercises great influence on the tenacity and elasticity of the fibre, increase of moisture diminishing the tenacity but increasing the elasticity.

—R. B. B.

*Connection between Tenacity of and Moisture present in Hemp and Flax.* C. A. Lobry de Bruyn. Chem. Zeit. 17, 1432–1433.

In a previous paper on this subject (Chem. Zeit. 17, 172–173; this Journal, 1893, 825) the author showed that the effect of increased moisture present in fabrics of hemp and flax is to increase their tenacity. This he has fully confirmed by subsequent experiments. The trials were made with strips of the fabrics cut according to the warp, and each number given is the mean of three to six estimations.

The results with four samples were:—

A.		B.		C.		D.	
Moisture.	Breaking Strain.	Moisture.	Breaking Strain.	Moisture.	Breaking Strain.	Moisture.	Breaking Strain.
Per Cent.	Kilos.	Per Cent.	Kilos.	Per Cent.	Kilos.	Per Cent.	Kilos.
0	178	0	189	0	143	9	147
4.1	197	2.2	190	3.9	162	2.2	153
7.5	243	5.5	232	6.4	193	5	179
9.8	277	9	288	8.8	235	6.7	205
12	315	12	350	10.7	255	11.2	250
13.5	378	15	402	13.3	290	13.3	265
26.4	405	19.1	417	22	320	31	290
..	..	35	425	38	325	..	..

From these results it is seen that with increase of moisture beyond 15 per cent. there is but very slight increase in tenacity. This result does not agree with that described in the previous paper, the difference being possibly due to a tighter twist of the thread in spinning the yarn in the former instance.

It is difficult to give figures which are absolutely exact, as it is found that so-called air-dried cloth contains, according to season of the year, from 6.5–12 per cent. moisture. The condition of the surrounding air during the experiments also affects the results. Different strips cut from the same fabric may show a difference of 5 per cent. in the breaking strain.

Hemp and flax are more hygroscopic than cotton; this may be due partly to difference of structure, partly to small quantities of pectic matters present in the hemp or flax. These substances may be present in scoured yarn even up to 10 per cent.—R. B. B.

*The Electrical Excitation of Petroleum Spirit (Benzene).* R. Kissling. Chem. Zeit. 17, 1773–1774.

In a letter on this subject the author states that in many chemical washing works it is customary to add a soluble soap to the petroleum spirit (benzene) in order to prevent the electrical excitation of this solvent. In some cases the soap is used all the time, in others it is only added when the crackling noise, which indicates the excitation, is detected. The fires that have not unfrequently broken out

in the chemical wash-houses, are attributed to extreme cases of the excitation referred to.—A. G. B.

*The Prevention of Petroleum Spirit Fires in Chemical Cleaning.* C. F. Göhring. Färb. Zeit. 5, 49.

When dried wool and silk are immersed in pure petroleum spirit (benzene), in the neighbourhood of an electroscope, lifted out and again immersed, a wide divergence of the leaves of the electroscope is observed. The amount of electricity may be even so great that it cannot be measured by the electroscope. If the experiment is conducted in the dark, electric sparks and flashes of light accompanied by crackling sounds are seen and heard, which may readily increase until the benzene is ignited. The method of prevention is to add to the benzene from 0.2 to 0.3 per cent. of a soap soluble in benzene, when the sparks and crackling at once cease and all danger is avoided.

It is well known that pure, freshly distilled benzene, in the cold, dry days of winter, is liable to take fire spontaneously, owing to the production of electricity. As soon as the atmosphere becomes warm or moist the conditions for carrying off the electricity, or for its total prevention, are secured.

In the first case mentioned possibly the soluble soap provides the necessary moisture, which by means of the soap is dissolved in the benzene, water being otherwise non-miscible with benzene.—R. B. B.

## VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

*Improvements in Bleaching and Printing.* Oesterr. Wollen- u. Leinen-ind. 1894, 14, 8.

As an improvement in calico-printing, the patent bowking process, already introduced into several printworks, is laid considerable stress on. The material is boiled in caustic soda-lye out of contact with the air, and an article is thus furnished which resembles half-bleached goods.

Reference is made to variegated goods, produced till recently for the most part in England, and it is stated that a strong effort is now being made to obtain appropriate shades that can be fixed on the material prepared with  $\beta$ -naphthol.

Success has been attained by printing with basic dye-stuffs with the addition of some tartaric acid and "tin salt," in obtaining effects similar to those obtained with paranitraniline red or naphthylamine Bordeaux.

After printing, the pieces are steamed, treated with tartar- emetic, and washed. As yet the whites in the case of paranitraniline red are unsatisfactory.

The discharge of direct-dyed colouring matters is carried out as heretofore; the extension of this branch is favoured by the fastness of the new direct-dyeing colours.

The discharge of basic colours progresses slowly; it is effected by means of caustic soda on the tannin-mordanted pieces, with subsequent treatment in tartar- emetic and dyeing with basic dye-stuffs. Chrome - discharged goods and resists with alizarin are produced in quantity. As suitable new colours, Alizarin green, Alizarin grenat, and Alizarin cardinal may be mentioned.

Repeated trials with the new judigo salt "Kalle" are in progress, though it would seem to be of interest for calico- printers only, on account of expense.—W. B. H.

*The Fixation of Uranium Oxide on Textile Fibres and the Application of Uranium Salts as Mordants for Dye-stuffs.* E. Odenheimer. *Färb. Zeit.* 5, 17—19.

**Uranium Yellow.**—This colour is produced by a method analogous to the author's process for "Golden purple" (*Bull. Soc. Ind. Mulhouse*, 1892, 529—539; this *Journal*, 1893, 432—443), the fabric impregnated with a uranium salt being subjected to pressure by a hot metallic surface. A bath containing 14 grms. uranium nitrate per litre gives an orange-yellow, more dilute solutions straw-yellow colours, while stronger solutions attack the fibre. The production of the colour depends on the formation of uranium hydroxide. It is affected by acids and alkalis.

**Uranium Brown.**—The fabric is first steeped in a hot solution of a uranium salt, then worked in either a solution of potassium ferro- or ferri- cyanide, or of gallic acid, hydro- quinone, tannic acid, or some tannin material. The brown obtained by the use of ferro- or ferri- cyanide is fast to acids, but destroyed by alkalis, while the colour produced by gallic acid, &c. is fast to alkalis, and destroyed by acids, the colour being restored by an alkaline solution.

These colours cannot be produced on cotton, and are darker on wool than on silk. They resemble very closely in appearance and properties the shades resulting from chromates and tannin materials, and in both cases there is little doubt that the colour is a true compound of tannin with uranium or chromium.

**Uranium Salts as Mordants.**—Experiments have been made with about 200 dye-stuffs, both as to the alteration of shade on the fibre, and the formation of a lake with the colour solution. Although a few results appear useful, these mordants do not possess advantages which would make them of general practical interest. The usual effect of uranium mordants is to change yellow to orange, orange to light red, blue or red to black, the colours being fast to soap and alkalis, but in most cases affected by acids.

In boiling wool with a 0.2 per cent. solution of uranium acetate, after one hour the wool has taken up about 30 per

cent. of the salt, and after 2—3 hours' boiling the solution is completely decolorised.

The author has been unable to make use of uranium compounds in the production of aniline black.—R. B. B.

*The Substantive Dye-stuffs in the Dyeing of Half-Wool Goods.* F. Ackerman. *Färb. Zeit.* 5, 33—34 and 52—54.

The author refers to two previous papers which have appeared on this subject by Lindemann (*Färb. Zeit.* 4 [7]) and Mecklenburg (*Färb. Zeit.* 4 [17]).

The numerous difficulties attending the use of the "direct cotton" colours for wool and cotton unions are due to three facts—(1) the entirely different behaviour of different dyes towards the same material; (2) the different behaviour of the same dye towards different materials; and (3) that the methods of dyeing differ greatly from those previously in use. Minor differences are also due to varying relative proportions of cotton and wool in the mixed fabrics.

As to the best method of dyeing, the author considers a boiling dye-bath indispensable, especially for thick and heavy goods. The best addition to the dye-bath is 20 grms. sodium sulphate per litre. Sodium bisulphate is not recommended.

According to results obtained on half-wool material the dye-stuffs may be grouped into six classes, as shown in the table on next page. In every case the dyeing was for two hours, boiling.

Most of these dye-stuffs tend to dye the cotton at first, the colour being only taken up by the wool after long boiling; hence if the time is less than two hours the division into groups will not be as above, e.g., a colour might appear in Groups 1 or 3 which is classed above in Group 2. The dividing lines between the various groups are of course not very clearly defined. The next question is, which groups of dyes are adapted for the dyeing of unions? That the dyes of the first group are so is evident, but the use of these alone does not afford a sufficient range of colours. Several of those in Group 2 are useful, viz., those which border closely on Group 1, such as Diamine Red NO, Benzopurpurin 4 B, Congo Red R, and Deltapurpurin 5 B, and, with a shorter time of dyeing, these may be counted in Group 1. The same applies to Chicago Blue. Or other dyes of this group may be used in mixtures with Groups 3 or 5. Diamine Searlet B and Diamine Fast Red F give good results at 70—80° C., the goods remaining after dyeing in the bath until cold. Diamine Fast Red F has the special advantage of great fastness to light. The dyes of Group 3 are applied together with Group 2 or with acid dyes for the wool, as mentioned later. Group 4 is unsuitable. Dyes of Group 5 are used in connection with acid dyes, and this is the case also with Group 6, the wool being shaded up to the cotton by the acid colour.

Sulphonyanin and Brilliant Sulphonazurin (Farbenfabriken), which dye the wool only, can be used with the blues of Group 5.

A number of acid colours can be applied to wool with the sole addition of sodium sulphate, though the bath is not thereby exhausted. Such colours are suitable for mixing with dye-stuffs dyeing cotton deeper than, or a different shade from, wool. Examples of these acid dyes are:—Azoflavine (B.A.S.F.), Croceine Orange (Kalle), Acid Violet 6 B (Bayer), Formyl Violet (Cassella), &c. Alkali Blue may be employed with those cotton colours unaffected by acids, if the goods are developed in a weak, cold, sulphuric acid bath. For shading are also useful:—Milling Red R (Cassella), Fast Acid Violet (ML and B), Rosinduline (Kalle), &c.

Every shade can be obtained by the various methods indicated except bright greens, blue-violets, and a brilliant black to compete in the matter of cost with logwood.

The following methods may be specially recommended:—

**Yellow.**—Oxyphenine alone, Direct Yellow with Diamine Gold or with Chrysophenine.

**Orange.**—Direct Orange with Croceine Orange.

**Red.**—Diamine Fast Red F, Diamine Searlet B, or Benzopurpurin 4 B.

**Light Blue.**—Diamine Blue with Alkali Blue 6 B. This shade is not fast to light.

**Brown.**—Diamine Bronze G with Brilliant Sulphonazurine and Congo Brown G.

In dyeing a second lot of goods in an old bath the amount of sodium sulphate used must be greatly diminished. To arrive at good results the bath should be tested with the hydrometer. The correct strength of the liquor is  $2\frac{1}{2}$ —3° B.

The effect of large quantities of sodium sulphate is to swell out the wool, at the same time giving it a flabby feel. The increase of volume may be preserved and the flabbiness avoided by an addition to the bath of  $1\frac{1}{2}$ —2 grms. of starch or gum.—R. B. B.

*The Production of many-coloured Fabrics by Mordanting the Yarn before Weaving.* H. Lange. *Färb. Zeit.* 5, 49—52 and 67—71.

THE production of parti-coloured fabrics, consisting of two or three different fibres, by choosing suitable colouring matters and methods, presents little difficulty. For example, with a mixed wool and cotton fabric the wool is dyed with an acid colour, the goods treated with tannin and an antimony salt, and then with a basic colour, the cotton becoming dyed and the wool shade being modified. With the benzidine colours good results may be obtained if it be remembered that in an acid bath wool and silk are dyed more than cotton, while in a neutral (salt) bath the cotton acquires the deeper shade, this being the case to a still more marked extent in an alkaline bath.

Fabrics of wool and silk are dyed in two colours by dyeing the wool with certain acid colours (e.g., Orange II) in a boiling bath, removing as far as possible the faint colour from the silk with boiling distilled water, or by other means, and then dyeing the silk in a warm bath with another acid colour (e.g., Water blue).

The special processes indicated in the title of the paper are applicable to fabrics of wool, cotton, or silk, or to mixed fabrics containing two or all of these fibres.

With fabrics of one fibre only, one method is to weave mordanted with unmordanted yarn, and then dye with some colour requiring a mordant. Then pass through a weak soap bath to remove colour from the unmordanted portions, and if necessary top with some basic, acid, or benzidine dyestuff. If three or more shades are desired, then unmordanted yarn is woven with yarn treated with salts of chromium, aluminium, iron, &c., and the fabric dyed with alizarin, logwood, &c.

Similar methods may be used for mixed fabrics, e.g., unmordanted and mordanted cotton, unmordanted and mordanted wool are all woven together, and dyed in one bath, cleared with soap, and perhaps topped with a second dyestuff, which may dye the wool only, the cotton only, or both fibres.

Numerous examples are given, illustrating these processes as applied to all classes of fabrics. This method has for some time been employed in the production of black fabrics with undyed margins, the main part of the fabric being woven from wool and mordanted cotton, while the edges consist of unmordanted cotton.—R. B. B.

*The Electrolytic Reduction of Indigo.* J. Mullerius. *Chem. Zeit.* 17, 1454.

THE possibility of reducing indigo by electrolysis was first demonstrated by Goppelsroeder. An electric indigo vat would possess the very great practical advantage of not containing any sediment which from time to time has to be removed, thus causing an interruption in the working of the vat. Having prepared a vat by electrolytic reduction of indigo, it would be necessary to pass through this vat while it is being used a feeble electric current. But Goppelsroeder, as also Wartha, observed that prolonged electrolytic treatment causes a further change of the indigo white, or even its total destruction, and for this reason the practical use of this vat is impossible. The electrolytic reduction of indigo cannot be satisfactorily effected in the

cold, but is easily accomplished at the boiling temperature. On the other hand, solutions of indigo carmine are easily reduced by the electric current even in the cold.—C. O. W.

*The Reduction of Indigotine to Indigo White.* F. Goppelsröder. Chem. Zeit. 17, 1633.

The reduction, or rather the hydrogenation of indigotine, for the purpose of forming a vat, can be effected in the presence of an alkali by various substances, some of which act in the cold, while others require higher temperatures. In the cold vats, which are especially used for the dyeing of cotton and linen, ferrous sulphate, zinc dust, glucose, hydro-sulphite, stannous chloride, and arsenic, or stannous chloride and orpiment, are used as reducing agents; while of the warm vats, which are used for the dyeing of wool and silk, the wool vat, the soda or potash vat, and the urine vat are those generally employed. Mixtures of indigo and various alkalis were subjected to the action of electric currents of varying power, but the reduction of the indigo was in every case found to be exceedingly slow and imperfect in the cold. At a boiling temperature, however, it proceeds very rapidly, but the prolonged action of the electric current upon the vats obtained, leads to further changes of the indigo white, and finally altogether destroys it. By impregnating cloth with a suspension of finely-ground indigo in a solution of caustic soda or lime and passing the cloth in contact between two copper plates forming the electrodes, and then sending an electric current through these plates, reduction of the indigo on the cloth takes place, and on subsequent exposure of the cloth to the air, it becomes dyed with indigo.—C. O. W.

*The Synthesis of Azo Colours on Animal Fibres.* J. Pokorny. With Report on the same by P. Werner. Bull. Soc. Ind. Mulhouse, 1893, 282—287.

Wool and silk possess the property of attracting from an aqueous bath certain amines, e.g., naphthylamine, provided that the amines are present as bases, and in a finely-divided condition. Naphthylamine is dissolved in alcohol, the solution poured into the bath, in which the wool is steeped over night. The next day the wool is passed through a solution of sodium nitrite acidified with hydrochloric acid; after some minutes the colour is developed, when the wool is taken out, washed, and dried. The colours are fast to soaping. The quantity of amine determines the depth of the shade. In the nitrous acid bath part of the naphthylamine is first diazotised, and the diazo compound combines with the remainder of the naphthylamine to produce the corresponding amido-azo body. The colours are only formed on wool or silk. Stannous chloride decolorises the fibre.

All amines which have the para-position free, and which are capable of yielding amido-azo compounds behave in a similar way.  $\alpha$ -Naphthylamine yields brown,  $\beta$ -naphthylamine, orange-red colours. For printing, the amine, together with thickening, is printed on the fabric, which is then passed through the nitrous acid bath to develop the colour.

The fixation of the amine on the fibre in the first bath is entirely mechanical, and it can be completely removed by washing with hot water.

Wool and silk prepared with naphthylamine and exposed to sunlight become darker. Brown or orange designs on a lighter ground can be obtained by preparing with naphthylamine, exposing portions of the fabric to sunlight, and developing with nitrous acid, when the exposed portions take a much darker colour than the covered portions; this is especially the case when  $\alpha$ -naphthylamine is used.

(It may also be noted that if wool or silk are steeped in a solution of a diazo or tetra-azo body, e.g., compounds derived from naphthylamine or di-anisidine, the fibre absorbs the azo-body, which can be converted into a useful colouring matter by further combining it with a phenol or amine.)

*Report by P. Werner on the above Paper.*—In carrying out the process described in detail in the foregoing, it is necessary to use alcohol and water in proportions depending on the nature of the amine. Thus, with  $\alpha$ -naphthylamine

(5 grms. per litre of liquid), as the amount of alcohol increases from 50 to 300 grms. per litre, the quantity of naphthylamine absorbed by the wool also increases. With larger amounts of alcohol it again decreases, until, with a bath consisting entirely of alcohol, no naphthylamine is absorbed. It appears, from experiments made, that the wool absorbs not only the dissolved naphthylamine, but also a part of the precipitated base, not by direct contact of the fibre with the precipitate, but through the medium of the liquid. The fact is, probably, that the naphthylamine passes from a medium in which it is less soluble, viz., water, to one in which it is more soluble, viz., wool. This absorption must take place in a bath in which the naphthylamine is to some extent soluble. Only the colours resulting from the use of  $\alpha$ -naphthylamine are of practical interest.

—R. B. B.

*The Action of Light on Metatungstate of Soda and its Applications.* C. Schoen. Bull. Soc. Ind. Mulhouse, 1893, 277—279.

If cotton be worked in a solution of metatungstate of soda of 5 per cent. strength, it rapidly becomes blue when exposed to light, owing to the reduction of the compound. In a dark room the fabric again becomes white, the blue colour re-appearing on renewed exposure to light. On treating the blue fabric with water a blue solution is obtained, which, on the addition of lead acetate, gives a blue precipitate. Both the solution and precipitate rapidly became colourless, even in full daylight. A simple solution of the metatungstate does not change colour. The effect of adding a salt of copper to the metatungstate is to retard though not to prevent the action of light; fabrics prepared with metatungstate and a copper salt become at first yellower and then slowly bluer. The reducing action of light is partly overcome by the oxidising properties of the copper salts.

—R. B. B.

*An Aluminium-Bronze "Doctor" for Printing-Machines.* (Reports on a "Doctor" sent in Competition for a Prize of the Society.) Bull. Soc. Ind. Mulhouse, 1893, 270—272.

(1.) *Report of M. Albert Frey.*—The new doctor has been in use for six months with satisfactory results. It presents a great advantage over the steel doctor with colours containing sodium bisulphite, which substance readily attacks steel, e.g., Coerulein S, Alizarin Blue S, &c. For reds and pinks also, the results are better than with doctors of either steel or ordinary bronze.

(2.) *Report of M. Albert Scheurer.*—The new "doctor" is superior to any previously made of the same material and to the "composition" doctor, but lacks the power of giving such clear and finished printing as is obtained by the use of the steel doctor. It does not, therefore, entirely fulfil the conditions of the prize, viz., that the doctor should offer the resistance of steel to mechanical work, and the resistance of "composition" to chemical agencies.—R. B. B.

*The Dyeing of Light Shades on Wool by Means of Alkalin Solutions of Alizarin Cyanine.* E. Schnabel. Farb. Zeit. 5, 145—147.

Like other alizarin dyestuffs, alizarin cyanines are soluble in caustic alkalis, alkaline carbonates and silicates, and borax. If wool is steeped in a hot alkaline solution of alizarin cyanine it is dyed, according to the shade of dyestuff, reddish-grey to light violet-blue. These colours are very fast to washing and fairly fast to milling, and approach in brilliancy the shades obtained with aniline colours, e.g., methyl violet. In choosing the alkali, sodium hydrate and carbonate are excluded owing to their effect on wool, and, in practice, ammonia is found most suitable. The bath must not be brought to the boil and the time of dyeing must not exceed 30 minutes, as hot ammonia solutions tend to mat and felt the wool. The method of dyeing, which is only suitable for loose wool, is as follows:—

The bath is heated to 85° C., when the alizarin cyanine, dissolved in 3–4 times its volume of liquor ammoniac, is added, and in addition 3 litres ammonia for every 50 kilos. wool. Enter the wool, and work 20 minutes at the same temperature. Take out, allow to cool, and rinse. The ammonia left in the wool quickly evaporates. After rinsing and drying, the wool, which becomes slightly matted during dyeing, recovers its original properties unimpaired. The dye-bath may be utilised for a second lot if certain proportions of alum and bran are added and the scum taken from the surface, whereby soap, &c. dissolved off from the first lot of wool are removed.

The disadvantages of the process are that, owing to the short time of dyeing, it is impossible by additions of dye-stuff to match a given shade, and that the colours are, as might be expected, sensitive to acids, the effect of which is to redden the shade. The former disadvantage is obviated by the fact that the dyer is soon in a position so to arrange the concentration of the bath that the desired tone may result, as the same mark of dye-stuff with the same amount of alkali gives always similar results.

The method is specially useful for pearl greys and light indigo blues. The colours withstand the action of sunlight better than the shades obtained with methyl violet or with indigo extract and orchil.

It is as yet difficult to say whether these colours should be classed as substantive or adjective, *i.e.*, whether the ammonia merely acts as a solvent, or whether it plays the part of a true metallic oxide.—R. B. B.

#### *Some Notes on the Dyeing of Logwood on Cotton.*

W. Bungert. *Färb. Zeit.* 5, 129–130.

When cotton is dyed by means of logwood extract and copper sulphate, the addition of tannin to the logwood tends to render the shade lighter. This appears to be due to the acid nature of the tannins, the same effect being noticed when acetic acid is added to the dye-bath. In the case of logwood extracts containing tannin this defect can partly be overcome by the addition of small quantities of soda to the bath, but the shade is not so dark even with this precaution, as when pure logwood extract is employed.

If, however, the logwood is applied by means of iron mordant, the addition of tannin darkens the shade. It is much better that the dyer should add the tannin extract to the logwood, than that he should use impure logwood extracts containing tannin. The best tannin material to use is chestnut extract, which tends to render the shade yellower, thus converting the logwood blue-black into a dead black, and rendering unnecessary the addition of a yellow colouring matter.

Although the deepest shades are obtained without alkali, in practice  $\frac{1}{2}$  per cent. of soda is added to the dye-bath; this causes the dyeing to take place more gradually, and therefore more evenly.

When a yellow dyewood is used to produce a dead black with logwood, either fustic or quercitron bark is chosen. The latter gives a darker shade with iron mordants, owing to the greater amount of tannin it contains, but for the best blacks a fresh logwood decoction is employed, together with pure fustic extract.—R. B. B.

#### *The Dyeing of Paper in Pulp.* H. Falke. *Färb. Zeit.* 5, 97–100 and 113–116.

A COLOURING matter to be suitable for paper-dyeing must possess a certain fastness to light, must not rub off, and should not injuriously affect the strength of the paper. The mineral colours have been largely used for this purpose, and the effect of the deposition of mineral particles in the fibre is that the paper becomes tendered. The coal-tar dyes are largely replacing the mineral colours, but the following of the latter class are still used:—

**Red Dyes.**—Vermilion, cinnabar.

**Yellow and Orange.**—Chrome yellow, ochre.

**Blue.**—Prussian blue, ultramarine, smalt.

**Green.**—Chrome yellow with Prussian blue.

**Black.**—Lampblack, graphite.

Of the vegetable colouring matters only logwood, catechu, and occasionally fustic are employed. The two former are used with potassium bichromate, alum, and nitrate of iron in the production of a black.

**Coal-tar Colours.** If the colour solution is merely mixed with the pulp, the greater part of the dye is carried away in the waste drained-off water. It is necessary to precipitate the dye-stuff in an insoluble form, *i.e.*, a mordant is required. Fortunately the substance used as sizing for the paper may act also as a mordant. The best substance of this class is the resin-soap made from colophony. This soap in solution is added to the pulp, and, after thoroughly grinding the mass, aluminium sulphate solution is poured in. Insoluble aluminium resin-soap is formed, and this serves as a mordant for both basic and acid dyes. With the former the colour precipitate consists of resinate of colour base and resinate of alumina, and with acid dyes of a compound in which aluminium is combined both with the colour acid and the resin acid. It follows that the amount of resins up must bear a definite ratio to the amount of dye-stuff, *e.g.*, water-blue and ponceau require 3–4 times and crystal violet 2½ times their weight of resin, in the form of soap, for complete precipitation. For thorough penetration of the pulp by the colour, it is best to add the soap and dye-stuff first, followed by the aluminium sulphate.

The following dyestuffs are completely precipitated by aluminium resin-soap, and the waste water is almost colourless if correct proportions of mordant and dye are employed:—

Cotton-scarlet.	Mandarin.
Rosecelline.	Orange II.
Croceine orange.	Metanil yellow.
Azotavin.	Victoria blue.
Diphenylamine orange.	Induline.
Indazine.	Phosphine.
Nigrosin.	Bismarck brown.
Brilliant crocein M.	

When the basic colours are applied to a paper which is only slightly sized, tannin and sodium acetate are added to complete the precipitation.

Too quick drying and too hot calendering injuriously affect the shade, rendering it duller.

The direct cotton dyestuffs can be fixed on paper by simply mixing their solutions with the pulp. Owing to their comparatively high price they are as yet only used for specially fine qualities. Many of them are exceedingly fast to light on paper, though this quality is not always of importance.

The dyes chiefly used for paper, besides those in the above list, and not including direct cotton colours, are:—

Water blue.	Safranine.
Hochst scarlets.	Brilliant green.
Eosine.	Malachite green.
Rose bengal.	Erythrosin.
Magenta.	Phloxin.
Acid brown.	Methyl violet.

In dyeing paper to match a given shade a preliminary trial should be first made with small quantities of material and the correct proportions thus ascertained. In matching a sample with the pattern, care must be taken that both are in the wet or both in the dry condition.—R. B. B.

#### PATENTS.

*Improvements in Machines for Dyeing and Securing Yarn.*  
J. M. Collins, Bridgeton, Glasgow. Eng. Pat. 977.  
January 17, 1893.

THIS refers to certain improvements in the machine described in a previous patent granted to the same inventor (Eng. Pat. 14,507 of 1892; this Journal, 1813, 825). The yarn-carrying poles are made in sections, capable of being reversed or interchanged, the end of each section being so formed that it can interlock with the end of the adjoining section. The poles are revolved by means of gearing fitted on the machine; this gearing drives a socket spindle for

each pole, into which the end of the pole firmly locks. Special rods are also provided for keeping the yarn stretched, and these are fixed in such a manner that they do not turn with the yarn.—R. B. B.

*Improvements in Bleaching and Discoloration.* J. Clapham, Bradford, J. Picard, Paris, C. Villedien, Paris, and W. W. L. Lishman, Brautord. Eng. Pat. 1623, January 25, 1893.

This invention relates to bleaching cotton, linen, flax, wool, leather, wool, &c., and in addition to the use of alkaline boils, includes a preparation of the material with olein soap, &c., followed by a treatment with permanganates and bisulphites, or, in lieu of the latter, with peroxides or alkaline chlorites. It is claimed that the preparation with the fatty body protects the fibre from the destructive action of the oxidising agents subsequently applied to it.

—W. E. K.

*Improvements in Printing and Dyeing on Fabrics.* O. Osteretzer, Sagan, Germany. Eng. Pat. 2153, January 31, 1893.

This invention relates to the production of discharge effects by the use of direct-dyeing colours which are capable of diazotisation on the fibre. The ground shade is dyed with a colour capable of destruction by means of reducing agents (diamine black, diazine, &c.), whilst the discharge is printed with a colour incapable of being so destroyed (primuline). After the discharge is effected the colours are then diazotised on the fibre and combined with a phenol or amine. For example, a Turkey-red shade on dark blue is produced as follows:—The cloth is dyed with diamine blue black E, a discharge containing primuline, zinc dust, and bisulphite is printed upon the dyed cloth and then steamed. The goods are then treated with muriatic acid, diazotised with sodium nitrite and hydrochloric acid, and lastly passed through a bath of  $\beta$ -naphthol and caustic soda. A blue print on a black ground is obtained in a similar way by dyeing with diamine black and developing with phenylenediamine.

—W. E. K.

*Improvements in Machines for Washing, Bleaching, Mordanting, Dyeing Cotton, Wool, or other Fabrics in a Raw, Spun, or Manufactured State.* C. Owens, Lower Broughton, and J. Whiteley, Salford. Eng. Pat. 4437, March 1, 1893.

The fibre is fed on to a revolving, perforated, endless table, and as it passes along is subjected to the action of water or other liquid, by means of jets placed above the table. After traversing the length of the machine the fibre is automatically passed between rollers. If necessary, a second table is provided underneath the first, in order to receive the fibre as it comes from the rollers and convey it back to the feeding end of the apparatus for a second similar treatment.

—R. B. B.

*The Production on the Fibre by the Aid of p-Amidodiphenylamine of Dye-stuffs fast to Light and Washing.* S. Pitt, Sutton. From L. Cassella and Co., Frankfurt-on-the-Maine. Eng. Pat. 1612, March 2, 1893.

This invention relates to the production of fast dyes from p-amidodiphenylamine by conjugating with diazo compounds produced directly on the fibre: such combinations being capable of production only on the fibre and not in solution. For instance, to obtain a dark blue fast to light and washing, cotton is dyed with diamine blue-black E, diazotised on the fibre with sodium nitrite and hydrochloric acid, and then passed through a bath of p-amidodiphenylaminehydrochloride.—W. E. K.

*Improvements in Apparatus for Dyeing and Washing Yarn in the Hank.* J. Rhodes, J. Rhodes, jun., and A. B. Perkins, Bradford, Yorks. Eng. Pat. 5291, March 11, 1893.

The apparatus consists of a framework, fitting inside the dye-vat, and provided with a number of cross rollers or hank-carriers, which have one end free to allow of the hanks being placed thereon. The whole framework with the rollers can be moved from one vat to another. Special rollers are also provided for keeping the yarn in a stretched condition in the vat. A feature of the apparatus, fully described and illustrated in the specification, is an arrangement of worm wheels for driving the rotatory hank-carriers.—R. B. B.

*Method of Producing Light Prints or Designs on Dark Ground, or for Producing Coloured Prints by Means of the Printing Press.* C. Vogel, jun., Gertrude a. Harz, Germany. Eng. Pat. 5397, March 13, 1893.

The print or design is produced on paper with light-coloured or white printer's ink prepared with oil, fat, or resin; and the surface is subsequently covered with water-colour, by means of rollers or other devices. As water will not mix with oil, &c., the water-colour adheres only to those portions of the surface which have not previously received an impression.—R. B. B.

*Improvements in Resists or Discharges for use in Printing or Dyeing Cotton, Wool, and other Fabrics with Aniline Black.* W. T. Whitehead, Magog, Canada. Eng. Pat. 7350, April 11, 1893.

This invention consists in the use of metallic zinc or any zinc compound (and by preference oxide of zinc) as a resist for producing white patterns on aniline black grounds. For producing coloured patterns an addition is made of a pigment and albumin, or of a coal-tar or extract colour, to the white resist (this Journal, 1893, 1627).—W. E. K.

*Improvements in Resists or Discharges for use in Printing or Dyeing Cotton, Wool, and other Fabrics.* W. T. Whitehead, Magog, Canada. Eng. Pat. 7351, April 11, 1893.

This invention consists in producing patterns in which the figure is of a shade contrasting with the ground, by printing the pattern with a resist containing zinc or a zinc compound and then dyeing the cloth with a plain colour in any well-known manner. A coal-tar, extract, or pigment colour may be added to the resist in order to vary the contrasting colour effect.—W. E. K.

*Improvements in the Production of an Indigo Vat or Bath employed in the Dyeing with Indigo.* Read, Holliday, and Sons, and H. Bindeschadler, Huddersfield. Eng. Pat. 7487, April 12, 1893.

This refers to an improvement in the hydrosulphite vat. At present sodium hydrosulphite is formed by the action of zinc on bisulphite of soda, and added to the ground indigo together with an alkali, usually lime, in sufficient quantity to dissolve the indigo white. According to this patent, instead of lime, caustic soda or potash is added in sufficient quantity to dissolve the indigo white, and also to redissolve the zinc hydrate precipitated by the first addition of alkali; thus producing a clearer vat with beneficial results.—R. B. B.

*Improvements in Dyeing Apparatus.* E. Gessler, Metzingen, Germany. Eng. Pat. 7841, April 18, 1893.

The material is wound on to a perforated spool. Into the upper part of each spool fits a regulating pipe, also perforated, and to the top of this are attached metallic rods forming a cross, from the four ends of whose arms depend hooks. These hooks are fastened into the material on the spools during dyeing. Each spool fits underneath on to a

support, which in its turn fits into a conical orifice in the false bottom of the dye-bath, and the spools thereby are firmly fixed to this bottom.

The dye-bath consists of a vessel with a false bottom, and is provided with a lid. A second large vessel or receiver, and two vacuum vessels, also form part of the apparatus, the dye-bath being connected with the receiver and vacuum vessels by suitably arranged pipes and taps. By means of one vacuum vessel the dye-bath is emptied of air, when the dye liquid flows into it from the receiver in such a manner that the liquid passes through the material from the outside, and is drawn off from the inside of the hollow spools into the second vacuum vessel. Thence it flows back into the dye-bath, passing through the fibre in the reverse direction. When these operations have been repeated sufficiently often, the spools are removed and the material dried in a centrifugal machine.

The regulating pipe ensures that all the liquid shall pass through the material. This is effected by the regulator automatically altering its length when the material is compressed on the spool, so that none of the perforations in the latter are left uncovered.—R. B. B.

*Improvements in Dyeing certain Colours on Cotton Fabrics and Yarns.* A. B. Hay and J. M. Park, Glasgow. Eng. Pat. 7919, April 19, 1893.

GREY shades are produced by fixing on the fibre a mixture of manganese and chromium oxides, brown and olive shades, by a mixture of manganese and iron oxides. For greys the cotton is impregnated with a solution containing chrome alum and manganese acetate, for olives and browns with acetates of manganese and iron. After treatment with the metallic solutions, the fibre is partially dried and passed through a weak solution of an alkaline hypochlorite at 150° F., the oxides being thereby precipitated. The colours are described as "fast and permanent."—R. B. B.

*A Process for Colouring Paper and Cardboard.* F. R. Wells, Southgate, Middlesex. Eng. Pat. 8167, April 22, 1893.

THE colouring matter is mixed with gelatin, starch, dextrin, or some other sizing material which is affected by chromium compounds, and a solution of a chromium salt or chromate. This mixture is either applied to the surface of the paper or incorporated with the pulp during manufacture. Or the colouring matter and size are first applied to the paper, which is then treated with the chromium solution.

In every case the paper or cardboard must be exposed to light or kept some time before use.—R. B. B.

*Improvements in or Appertaining to the Utilisation of a Waste or Nearly Waste Product, and the Manufacture of a Useful Gum or Gummy Compound therefrom.* J. Hanson, P. C. D. Castle, and J. H. Morrison, Liverpool. Eng. Pat. 8793, May 2, 1893.

See under XVI., page 410.

*Improvements in Yarn-dyeing Machines.* J. G. Haslam, Philadelphia, U.S.A. Eng. Pat. 18,517, October 3, 1893.

THIS invention embodies several improvements in the apparatus described in Wolstenholme's patent (Eng. Pat. 2060 of 1889; this Journal, 1889, 329). The improvements are as follows:—(1) The necessity of disconnecting the yarn frame from the lifting devices, in order to reciprocate the former in the dye-liquor, is avoided; (2) an arrangement whereby the sets of yarn sticks may be moved nearer together or further apart to suit the size of the skeins; (3) the adjustment of the yarn sticks is accomplished through the supports for the upper set of sticks, instead of the lower, so that adjustment may be brought about while the frame is lowered, and the yarn submerged in the liquor; (4) the employment of indicating devices which register the number of reciprocations imparted to the yarn frame.

In addition, certain minor improvements are described, which, together with those mentioned, are minutely set forth in the specification, and illustrated in the drawings accompanying the same.—R. B. B.

*Apparatus for Dyeing and Washing Loose and Spun Wool, Cotton, and such like Material.* E. Labhardt, Basel, Switzerland. Eng. Pat. 20,257, October 27, 1893.

Into a boiler containing the washing or dyeing liquor, a perforated basket fits exactly at the sides, but so as to leave a space below it in the boiler. The basket rests on the rim of the boiler by means of rollers allowing it to be rotated as required, and is divided into two or more compartments by perforated horizontal partitions. The liquor is brought to the boiling point and kept constantly in whirling motion by means of suitably arranged steam injectors. The action of the steam causes the liquor to pass downwards through the fibre in the basket to the lower part of the boiler, from whence it passes upwards by pipes, and thus again into the upper compartment of the basket. An injector is also arranged so that steam can be passed upwards into the basket, when necessary, in order to loosen the material contained therein.—R. B. B.

*An Improved Process of Dyeing for Producing Genuine Turkey Red and Rose Colour in Vegetable Yarns in Cops, Hanks, Carded Strips, and the like.* W. P. Thompson, Liverpool, Manchester, and London. From E. Holken and Co., Barmen, Germany. Eng. Pat. 23,559, December 7, 1893.

THE cops or hanks of yarn are oiled and mordanted with alumina in the usual manner, and the mordant fixed by means of borax. The novelty of the process consists in the alizarin dye-bath being cold and extremely concentrated, excess of alizarin being removed from the fibre after dyeing by treatment with suitable solutions (e.g. acidulated water). The depth of colour is regulated by the strength and composition of the alumina mordant. After dyeing, the yarn is oiled, and steamed under pressure, and finally cleared in a hot soap bath.—R. B. B.

*A Machine for Dyeing Hats, Caps, Stockings, and other similar Articles.* E. F. Liebt, Elberfeld, Germany. Eng. Pat. 520, January 9, 1894.

UP to the present the dyeing of these goods has been very difficult compared with yarn and piece dyeing, &c., the slightest inattention to minute details having disastrous consequences, and the expense being great.

The machine consists of two vessels, which can be used for mordanting and dyeing, or dyeing and washing. A cylinder of perforated wood or metal contains the articles to be dyed, and rotates within one vessel. The cylinder, which is constructed after the type of the paddle-wheel, is furnished internally with a number of "spokes" partly dividing it into compartments, and the rotation of the cylinder causes the articles to be continually thrown into those compartments coming in contact with the dye liquor.

By special mechanism the cylinder with the goods may be lifted out of the one vessel and placed within the other to undergo some further necessary process.—R. B. B.

## VII—ACIDS, ALKALIS, AND SALTS.

*Employment of Electrical Heat for Concentrating Sulphuric Acid.* C. Haussermann and L. Nothhammer. Chem. Zeit. 17, 1907—1908.

EXPERIMENTS on the concentration of sulphuric acid by means of electrically generated heat, as suggested by Bucherer (this Journal, 1894, 249), yielded very unsatisfactory results with continuous direct currents, owing to

electrolysis and consequent loss. Sulphur soon made its appearance, and sulphuretted hydrogen and other gases were evolved, the current partly passing through the acid by the shorter path. After  $2\frac{1}{2}$  hours, 42 grms. weight was lost by the acid; but the strength had only risen to 61 B., the loss being mainly due to decomposition, and not to evaporation. In another experiment under conditions again modified, considerable separation of sulphur and evolution of gases occurred, the acid itself acting as a second path to a large extent, and electrolysis consequently taking place: thus after 6 hours 190 grms. of 60° acid were reduced to 157 grms., but the concentration only rose to 62° B. It was ultimately found impracticable to diminish the resistance of the wire to such an extent as to render the branch current passing through the acid negligible, because in that case the heat developed (proportionate to resistance and square of current) would be insufficient for the evaporation; and with larger current strengths, the branch current, and consequently the electrolysis, would be also increased.

Somewhat better results, however, were obtained when alternating currents were employed; thus, under this condition, 190 grms. of 60° acid were concentrated to 65.8° B. (at 15°) with a loss of weight of 35 grms. in  $3\frac{1}{4}$  hours, the temperature rising to 286° and remaining nearly constant thereafter; the current employed was derived from a lighting supply of 110 volts and about 0.9 ampère, converted by suitable transformers into an alternating current of 6 to 7 volts and 14 ampères. No visible sulphur was formed, but a slight disengagement of gas occurred along the length of the wire. The energy consumed during the production of 155 grms. of concentrated acid accordingly amounted to  $14 \times 6.5 \times \frac{13}{4} = 296$  Watt-hours, or about 1,490 per kilo.—C. R. A. W.

*The Preparation of Ferrieyanide Salts. Preliminary Communication.* G. Kassner. Chem. Zeit. 1893, **17**, 1712.

IN 1889 the author proposed a method for the preparation of potassium ferrieyanide (this Journal, 1890, 391), based on the reaction between lead dioxide and potassium ferrieyanide in presence of carbonic acid gas, recommended by Lunge, but instead of lead dioxide the author used calcium plumbate with advantage for the conversion of ferro- into ferrieyanide salts. This compound is easily decomposed with separation of lead dioxide in the nascent state, by acids, ammonium salts, and carbonates and bicarbonates of the alkalis; in the latter case, the calcium carbonate also being made use of. By sodium carbonate at about 130° C., or under pressure, the decomposition is represented as follows:—

This insoluble mixture, which contains the lead dioxide in a finely-divided state, and is freed from sodium hydrate, is now caused to react with potassium ferrieyanide in presence of carbonic acid gas (on the large scale obtained from lime-kilns or coke-ovens) in the cold, according to the equation—

On evaporation of the clear liquor drawn off from the heavy insoluble residue which has settled down, the potassium ferrieyanide is separated from the potassium carbonate by crystallisation, the latter remaining in the mother-liquors.

The washed residue, consisting of lead monoxide and calcium carbonate, is employed for the regeneration of calcium plumbate. By the addition of calcium ferrieyanide, the potassium carbonate present is converted into potassium ferrieyanide, according to the equation—

The separation takes place easily on warming, the calcium carbonate quickly precipitating and settling down, whilst the potassium ferrieyanide is obtained on evaporation in good crystals.

It is indifferent whether the calcium ferrieyanide be added before or after oxidation, but the author prefers the latter for the following reasons:—

For completely carrying on the oxidation of the ferrieyanide, carbonic acid gas is necessary, by means of which the excess of alkali from the ferrieyanide salt, is converted into carbonate, and the dioxide of lead, after giving up its oxygen, into basic lead carbonate; but since carbonic acid is only slightly soluble in the liquid, the alkali acts as a carrier of this gas, in becoming converted intermediately into bicarbonate or sesquicarbonate.

The preparation of calcium ferrieyanide is analogous to that of the potassium salt by calcium plumbate; the latter is converted into a finely divided mixture of lead dioxide and calcium carbonate, and then treated with calcium ferrieyanide and carbonic acid gas, preferably under pressure. The reaction proceeds in the cold or warm, and in concentrated solution, as follows:—

Two molecules of hydrochloric acid are now added to the precipitated residue, after running off the supernatant liquor, to remove the excess represented by one molecule of calcium carbonate; the residue can then be worked up again for calcium plumbate. The calcium ferrieyanide solution is preferably used at once for treatment of the crude potassium ferrieyanide solution as above, or if required in the solid state, it must be evaporated in partial *vacuo*, since it is somewhat unstable.

The removal of alkaline carbonate is now only necessary to obtain a pure crystallised potassium ferrieyanide. For use as an oxidising and bleaching agent, the removal of the carbonate is not only unnecessary, but its presence is actually of advantage, since by the addition of calcium plumbate, the requisite quantity of caustic alkali is thus obtained (this Journal, 1890, 108).

By regular regeneration of materials, the process becomes continuous.—W. B. H.

*Manufacture of Barium Salts.* Chem. Zeit. **17**, 1847—1848; **18**, 67—68.

AMONGST the various barium compounds employed in industrial operations, three more particularly are in growing demand, viz., barium chloride, sulphide, and peroxide.

*Barium Chloride* is usually prepared either by acting on *witherite* (natural barium carbonate) with hydrochloric acid, or by heating together barium sulphate, small coal, and calcium chloride, when barium chloride is formed in consequence of the double decomposition ensuing between the calcium chloride and the barium sulphide first produced by the reduction of the sulphate. This latter method is carried out on the large scale thus:—240—250 kilos. of heavy spar, ground fine (containing 93—95 per cent. of actual  $\text{BaSO}_4$ ), are intimately mixed with 160—170 kilos. of calcium chloride (containing 70—75 per cent. of  $\text{CaCl}_2$ ) and 85—90 kilos. of coal dust, and charged into the hinder part of a roaster, where it is heated up for two hours, and is then raked into the front part, where it is further heated with frequent stirring, a fresh charge being introduced into the back part of the oven, so that two charges are in simultaneously, one heating up and the other being worked. In this way five charges per shift are worked off. Instead of fused calcium chloride, the mother-liquors from potassium chlorate manufacture are sometimes used. These are usually of density about 40° B., and contain a known proportion of calcium chloride. A measured quantity is intermixed with the appropriate amount of heavy spar and coal dust to a thick pulp, which is then dried in the oven; in consequence of the extra time requisite for evaporating off moisture, only four charges per shift are worked off instead of five; only one charge, moreover, can be in the oven at once, as the stuff spreads over the whole of the sole. When the operation is finished the fluxed mass is raked

out into conical iron moulds and cooled; the product is almost black, with a grey fracture; portions of unburnt carbonaceous matter should be present, otherwise the reaction is probably incomplete; on the other hand, flakes

of undecomposed heavy spar should be absent. The structure should be somewhat porous, otherwise the subsequent lixiviation will be difficult; with a successful melt 59–60 per cent. of  $\text{BaCl}_2$  should be dissolved out, with only 0.05–0.1 per cent. of S, the rest of the mass being mostly insoluble calcium sulphide; too large a proportion of calcium chloride must be avoided, otherwise the liquors become too soon highly charged with the excess of this salt. The lixiviation is carried out in iron tanks of  $3 \times 3 \times 1.5$  metres, five or six being connected together in a system; the melt, broken into blocks the size of a head, is filled into one of these, hot water run in, and the whole heated up by steam; the strong ley thus produced usually marks  $30^\circ$ – $31^\circ$  B., and is run off, an equal volume of hot water being simultaneously run in, so as to keep the level of the liquor constant; when the ley is thus reduced to  $24^\circ$ – $25^\circ$  B. the running off is interrupted. The mud is poked over with an iron rod to feel if any lumps of solid matter are present, in which case much barium chloride might be lost through defective solution; if the mud is free from lumps, the liquor, at about  $24^\circ$  B., in the tank is run off to a different reservoir, and the tank filled with water and boiled up. The final wash waters should not mark more than  $1^\circ$  B., containing only 0.4–0.5 per cent. of barium chloride; these, together with the previous weaker liquors ( $24^\circ$  B. downwards), are used instead of fresh water to lixiviate a new batch. The stronger liquors first run off ( $31^\circ$ – $24^\circ$  B.), are pumped into a tank in which they are treated with carbonic acid (lime-kiln gases) and steam, to decompose the small quantity of barium sulphide present, the blowing being continued until a sample of the liquor no longer gives a brown precipitate with basic lead acetate solution; this, as a rule, requires about two hours; after some hours standing at rest to settle, the clear hot liquor is treated with a little hydrochloric acid to neutralise it, and evaporated in iron pans until a pellicle forms on the surface (i.e., till the density is about 30 B.); it is then run into iron crystallising pans. To avoid discolouration of crystals by iron, the evaporating and crystallising pans are coated with enamel or other protective material. The mother-liquors are worked up along with a fresh batch of liquor, and so on until the quantity of calcium chloride present rises to about 200 grms. per litre; when this is reached the mother-liquors are further concentrated alone, so as to obtain a crop of impure barium chloride crystals, the final mother-liquors being worked up along with solid chloride of calcium, &c. in the charge for the roasting oven. If anhydrous powdered barium chloride is required, the first strong liquors are boiled down in a directly-fired pan so that fine crystals of barium chloride separate; these are fished out and dried in a calcining oven with continual stirring with iron rakes, and finally packed in wooden barrels. The product contains about 95 per cent.  $\text{BaCl}_2$ , together with a little calcium chloride and water.

**Barium Sulphide** is prepared in the same kind of roasters as are in use for the chloride, with the difference, as regards materials, that calcium chloride is omitted and some binding material (such as coal tar) used instead. After some  $2\frac{1}{2}$  hours' firing the melt is raked out into well-covered iron moulds to cool, and is then packed in barrels, &c. as

rapidly as possible. By exposure to air the lumps become covered with a white layer of  $\text{Ba(OH)}_2$  and  $\text{Ba(HS)}_2$ , owing to absorption of moisture; material thus altered is worked over again with a fresh charge. The analytical valuation is effected by treating a known weight with water and hydrochloric acid, filtering and washing into a graduated vessel, precipitating a known fraction of the fluid as sulphate, and reckoning the sulphate formed into  $\text{BaS}$ .

**Barium Nitrate** is manufactured from the chloride by dissolving in a copper vessel to a saturated solution of about 32 B., and thus adding the appropriate quantity of sodium nitrate; the difficultly soluble nitrate precipitates and is collected, drained, slightly washed with cold water, and recrystallised by dissolving up in lead-lined wooden tanks of  $1 \times 2 \times 0.8$  metre to a density of 24 B.; after settling for two or three hours the hot liquor is drawn off through a lead or rubber siphon into lead lined crystallising tanks of  $2.5 \times 1 \times 0.8$  metre; the crystallisation takes two to four days, according to the time of year. The mother-liquors serve to wash the first crystals of nitrate formed from the chloride; the first mother-liquors left in the copper pans contain little but sodium chloride, and are a waste product utilised as occasion serves, e.g., for preparing sal ammoniac; the second mother-liquors, after washing the crude crystals, are evaporated so as to obtain a crop of impure nitrate crystals; this is repeated, after which the amount of barium nitrate left is too little to be worth recovering; thus the second time affords a crystallisation containing only 8.2 per cent.  $\text{Ba(NO}_3)_2$ ; the third time, one containing only 2.2 per cent.

**Barium Peroxide** is manufactured from the nitrate obtained as above, by ignition in pots holding about 16 kilos. each, a series of 24 being heated simultaneously; the salt fuses and then becomes decomposed, solid baryta being ultimately left. Next day, when the pots have cooled sufficiently, the cakes of baryta are removed and broken up into fragments, about 1 cm. square and 3–4 thick; these are filled into iron boats or gutters, about 1 metre long, two of which are placed inside a cast-iron tube capable of being heated to a dull red heat; the arrangement shown in the figure is usually employed, three cast-iron tubes, *a*, *b*, *c*, being arranged parallel to one another in a double fireplace, their ends being united by the movable socketed cross-tubes *f* and *f'*, furnished with glass spy holes, *e* and *e'*, for judging the temperature of the tubes. *f'* communicates with the chimney at *x*, a damper being placed beyond *x* to regulate the draught, and another at *g*. The tube *c* is empty, only the other two, *a* and *b*, containing the boats, filled with baryta; these are introduced when the tubes are heated to a dull red heat and kept there for 3–4 hours, a stream of purified air being drawn through all the time; the purifier is indicated by *M*, and consists of an iron chest with a tightly fitting lid, *a*, filled up to the level *n* with lumps of caustic soda, so that the air passing through is deprived of moisture and carbonic acid. Finally, the barium peroxide resulting from the roasting of the baryta is picked over to separate imperfectly oxidised lumps, &c., and packed in strong paper-lined barrels of 200 kilos. each. Its chief use is for direct bleaching, and for the preparation of hydrogen peroxide, for which purpose sodium peroxide is also coming largely into use.—C. R. A. W.

## PATENTS.

*Improvement in the Manufacture of Soda and Monocalcic Phosphate.* F. Hurter, Widnes, Lancaster, and J. Omholt, Christiania, Norway. Eng. Pat. 7107, April 6, 1893.

THE residual ammonium sulphate solution obtained in the manufacture of soda from sodium sulphate by the ammonia-soda process, is evaporated to dryness, preferably in steel heat pans, and the dry salt is mixed with tricalcium phosphate (high grade native mineral phosphates being used in practice), the phosphate preferably in excess of the proportion indicated by the equation—

The mixture is heated to from 550° to 650° F. in a cast-iron horizontal retort, set in brickwork, and heated externally by direct fire, in a slow current of previously superheated steam. The ammonia evolved is led into cooling apparatus, in which a dilute solution of ammonium sulphate is collected, applicable in dissolving sodium sulphate to be treated by the ammonia-soda process. The dry ammonia is then conducted into absorbing apparatus to meet with fresh sodium sulphate solution. The contents of the retort are allowed to cool in an atmosphere of steam to about 220° F., a special inlet being provided for steam at atmospheric pressure only; the monocalcium phosphate then absorbs any water it may have lost at the higher temperature. The residue, consisting of monocalcium phosphate, calcium sulphate, and small proportions of ammonium sulphate, and unaltered tricalcium phosphate, is then withdrawn to be ground up as a manure, with addition of 10 or 15 per cent. of sulphuric acid of sp. gr. 1.60, if desired. If the mass becomes damp, it may be dried at a temperature not exceeding 212° F.—E. S.

*Improvements in the Manufacture or Production of Monocalcic Phosphate and Ammonia.* F. Hurter, Widnes, Lancaster, and J. Omholt, Christiania, Norway. Eng. Pat. 7108, April 6, 1893.

*Improvements in certain Apparatus for the Distillation of Ammoniacal Liquor.* F. M. Spence and D. D. Spence, Manchester, and J. Gilchrist, Lyndhurst, Manchester. Eng. Pat. 7485, April 12, 1893.

THE improvements relate to the construction of the vertical iron column containing overflow shelves projecting from alternately opposite sides used for the distillation of ammoniacal liquor by means of introduced steam. The column is made oblong in cross section, instead of square, in order to greatly increase the length of contra-current traverse between any two openings. The still is made, not only to distil off free ammonia; but for the reaction by milk of lime on ammonium salts, so that the ammonia from these also may be recovered in the same apparatus. As ammoniacal liquor usually contains both free and fixed ammonia, the shelves or diaphragms of the upper portion of the still are such in number as may suffice for the separation of the free ammonia, each shelf having a lip of sufficient height to maintain always a stratum of liquid upon it. But the first of the lower series of shelves has a much higher lip than any of those above or below, so that it may hold a considerable store of liquor, and into this receptacle a flow of milk of lime is introduced by a suitable pipe. The liquor received from the higher shelves mixes with excess of lime, and flows downwards from shelf to shelf, each lipped, like those of the upper series, having exit near the bottom by a suitable pipe. Steam is admitted, under pressure, near the bottom, and a dead-weight safety-valve is provided at the top of the still, which need not be constructed to resist more pressure than 10 lb. to the square inch. The top shelf is provided with a vertical plate near its closed end, to admit of retaining sufficient liquor to cover completely the perforated pipe, arranged transversely, into which the supply of ammoniacal liquor is led from a supply tank, having an equalising box with ball-valve. Opposite the lip of each

shelf is a manhole, closed by a lid held in position by cross bars, to admit of the free use of rakes or shovels for removing any pitchy or other matter that may accumulate.—E. S.

*Improvements in the Manufacture of Permanganates of Soda or Potash from Manganates of Soda or Potash.* J. Brock and F. Hurter, Widnes, Lancaster. Eng. Pat. 7512, April 12, 1893.

THE inventors have found that solid sodium or potassium manganate is difficult to convert into permanganate by carbonic acid gas; but that if a small proportion of water is added, as liquid or as steam, the conversion is greatly facilitated. The process is preferably conducted by spraying water, to the extent of about 20 per cent., on a layer of the ground manganate, which is meanwhile turned over or agitated. Should the powder cake, it is broken up or re-ground. The manganate is then charged into a revolving cylinder provided with breakers or stirrers, such as is described in Eng. Pat. 1213 of 1893 (this Journal, 1894, 38), and carbonic acid gas is passed in, and is rapidly absorbed by the hydrated manganate, with evolution of heat, the manganate being converted into solid permanganate, and any free alkali into carbonate or bicarbonate. The process may be modified by sending steam or a spray of water into the cylinder, instead of previously moistening the manganate; or the gas may be passed in moist, or with steam or spray.—E. S.

*Improvements in the Electrolytical Decomposition of Chlorides and Mixtures thereof, and in Apparatus for the Purpose.* F. M. Lyte, London. Eng. Pat. 7594, April 13, 1893.

See under XI., page 404.

*Improved Process for the Manufacture of Carbonate of Ammonia.* C. Raspe, Berlin. Eng. Pat. 7846, April 18, 1893.

LIQUORS containing ammonium carbonate, such as ammoniacal liquors from the distillation of fuel, bones, or the like, are freed from sulphur by agitation with suitable metallic hydroxides or with zinc carbonate. The liquor, to which sodium carbonate may be added, is then agitated with a "fatty oil" to remove a portion of the empyreumatic bodies, and is distilled in an apparatus having wide passages to obviate clogging. The ammonium carbonate vapours are passed through freshly-made, heated wood-charcoal to remove the remainder of the "empyreuma," and are condensed. "The drying of the carbonate of ammonia may also be assisted or performed by the use of drying materials, either with dry carbonates or with dry potash or soda."—E. S.

*Improvements in the Manufacture or Production of Soda Crystals.* H. R. Browne, Roselea, Lancaster, and M. Guthrie, Liverpool. Eng. Pat. 8907, May 3, 1893.

THE caustic soda liquor obtained by the electrolysis of brine, is agitated for some hours with the mixture of sodium carbonate and bicarbonate obtained in the ammonia-soda process, when the sodium bicarbonate produced in that process has been freed from ammonia and partially decarbonated by suitable heating. The proportions used of the caustic soda liquor and of the mixed carbonates are such as may result in the total formation of sodium carbonate, proportions determinable by any suitable tests. About 2 per cent. of salt cake and enough bleaching powder or liquor to oxidise any colouring matters that may be present, are added. The liquor should be of such density as to contain about 25 per cent. of sodium carbonate, and is cleared from insoluble matters by settling and decantation, and is then run into pans for crystallisation, the ordinary soda crystals ( $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$ ) being obtained.—E. S.

*Improvements in and relating to the Treatment of Salt, and the Formation of Blocks thereof by Fusion.* W. Haddan, London. From La Compagnie du Sel Agglomeré, Paris. Eng. Pat. 24,194, December 15, 1893.

SALT that has become agglomerated by moisture, is crushed by apparatus consisting of unchangeable metal, mill-stone, or other materials that will not soil.

Impure or discoloured salt is purified in various ways, according to the circumstances, as by solution and decantation, washing in saturated water, or mechanical processes. If organic matter is present, the subsequent process of fusion, with or without addition of a nitrate, gives a colourless product. Drying is sometimes advisable before fusion, and may be carried out in various ways.

*Fusion or Melting.*—Small quantities of salt may be melted in movable crucibles in any system of furnaces. The crucibles are of unattackable metal, refractory earth, or porcelain. For melting salt in larger quantities, a furnace is used having crucibles fixed in it, single or multiple; or with a fixed pan; or with a movable pan. The second type of furnace, with fixed pan, is shown in the drawings below; one an elevational and sectional view; the other a plan view and section.

Fig. 1.

Fig. 2.

The furnaces are constructed of materials containing little or no free silica, "such as magnesia, chalk, and particularly porcelain." The fuel used is preferably gaseous. The gas arrives through the conduit R, ending at the hot gas chamber Y, air passing through the conduits S, to end at the hot gas chamber Z; the gas and air then pass together into the furnace J, and afterwards into the flues F, the regenerators Q, and, lastly, the flues T. The furnace vault is pierced by many small orifices X, through which the salt is passed by a rotary apparatus. The

running off is through orifices kept at a high temperature, as at the outlet K. If the running off is to be continuous, the overflow chute O is used. The dimensions of the orifices are adjusted to the required rate of flow. The fused salt is run into moulds U, a series of which may be mounted on wheels and circulate in the tunnel V, where they cool down slowly. The moulds may be formed of nickel, aluminium, cast iron, &c., or of porcelain or the like.

The salt blocks obtained in these furnaces have a superficial layer of solid and hard crystal surface "resisting moisture." But in some cases it is preferred to dip the blocks, while hot, in melted paraffin; or a thin coating of an alkali silicate may be applied. —I. S.

*Improvements in Apparatus for the Electrolytic Decomposition of Metallic Salts.* C. Kellner, Vienna, Austria. Eng. Pat. 24,274, December 16, 1893.

See under XI., page 494.

*Improvements in the Art of preparing Solutions carrying Salts of Zinc.* P. C. Choate, New York, U.S.A. Eng. Pat. 456, January 9, 1894.

SOLUTIONS containing zinc salts are freed from other metals by subjecting them, in a vat supplied with suitable anodes and cathodes, to a current of electricity from a dynamo electric machine or otherwise. Part of the impurities are deposited upon the cathode, and part go down as precipitates. To prevent the solution becoming acid, purified zinc oxide is added, as required. The zinc oxide for this application is obtained by subjecting crude zinc "fume" or oxide to a moderate roast in a muffle furnace at a temperature from 500 to 800 F. In case lead is present in the solution electrically treated, it is thrown down as sulphate by addition of sulphuric acid. Pure zinc may, if desired, be deposited electrolytically from the solution purified as described.

Another method of purification is adopted for solutions of crude zinc sulphate, such as those obtained by lixiviating roasted sulphur ores of zinc. The cleared solution is crystallised, and the hydrated sulphates obtained are roasted at a temperature between 500 and 900 F., the mass being stirred. The product is treated with water, and the zinc sulphate solution is cleared from insoluble matters, which are reserved for metallurgic treatment. By this process, elements more volatile than zinc are volatilised, and those less volatile are converted into compounds insoluble in water. —I. S.

## VIII.—GLASS, POTTERY, AND ENAMELS.

### PATENTS.

*Improved Means for Ornamenting Pottery Ware.* H. L. Doulton and W. P. Rix, London. Eng. Pat. 2252, February 1, 1893.

THE pottery ware is ornamented by rotating it upon the mandril of a lathe and operating upon its face with a toothed wheel caused to roll along the work and travel in a direction parallel to the axis of rotation. —V. L.

*A Porous and Absorbent Material, chiefly applicable for Tobacco Pipes.* A. H. Smith, London. Eng. Pat. 5555, March 15, 1893.

THIS material, which is called by the inventor "Catharopyr," is made by adding asbestos fibre to a thin "slip" of fine pipeclay (or steatite, or both) mixed with water. The whole is worked up to a plastic mass, which is then moulded

into any required shape and baked in a kiln at a high temperature. The resulting material is refractory to heat, and at the same time is porous or absorbent. When fouled, as for instance, by nicotine, the material can be cleansed by being heated in the fire, after which the article is as good as new.—V. C.

*Improvements in the Glazing and Enamelling of Heavy Earthenware and other Goods, and in Apparatus to be Employed therefor.* T. W. Twyford, Hanley. Eng. Pat. 6612, March 29, 1893.

SMALL articles of pottery ware are readily glazed by dipping into the liquid glaze and then setting them to drain. This cannot be done with large and heavy articles, to which the glaze is generally applied by means of a camel-hair brush, two or more operatives working at a time. This operation has to be performed very quickly, and followed up closely to prevent the edges, which set rapidly, from being "overlaid."

In the present invention the glaze is applied in the form of a spray, the workman moving the spraying apparatus from one position to another until the whole surface of the article has been coated. The principal portion of the apparatus consists of two lengths of tubing converging to a common centre, one for the conveyance of the liquid glaze, and the other for the blast.—V. C.

*Improvements in the Manufacture of Compositions suitable for Paving, Building, Pipe-jointing, and other like Purposes.* W. Sykes, London. Eng. Pat. 7499, April 12, 1893.

ONE gallon of Archangel tar or of Stockholm tar is mixed with two bushels of Portland cement, and the mixture is worked up to a plastic condition. When required for paving, hard wood sawdust is first added to the tar, and during the process of incorporation with the cement the whole is heated in a cauldron. The composition is also suitable for forming damp-proof courses or for forming bricks for building in damp soil.—V. C.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*The Composition of Portland Cement.* B. Kosmann. *Thonind. Zeit.* 1893, 17, 1140.

IN opposition to the views held by Le Chatelier regarding the formation of the tri-basic calcium silicate,  $\text{Ca}_3\text{SiO}_5$ , and the hydrate,  $\text{CaSiO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$ , and the presence of the unstable, and therefore objectionable, di-basic compound,  $\text{CaSiO}_4$ , the author puts forth the following theory:—

Silicic acid corresponding to the hydrates with one and two molecules of water being represented by the formula  $\text{H}_2\text{SiO}_3$  or  $\text{SiO}(\text{OH})_2$  (meta-silicic acid) and  $\text{H}_4\text{SiO}_4$  or  $\text{Si}(\text{OH})_4$  (ortho-silicic acid), the constitution of the constitution of the compound  $\text{Ca}_3\text{SiO}_5$  must be—

The molecule  $\text{CaO}$  is only in loose combination, hence this compound immediately splits up when brought into contact with water. The tendency of the fused silicate,  $\text{Ca}_3\text{SiO}_5$ , to dissociate is supposed to be owing to the fact of the molecular equilibrium, and therefore the limit of the capacity to react farther not having been reached before solidification takes place. The decomposition of the compound may be explained by the excess of heat, taken up during fusion, being given up on solidification. This fact of the instability of the fused silicate,  $\text{Ca}_3\text{SiO}_5$ , does not, however, prove the correctness of the supposition that the

hydrated compound,  $\text{Ca}_2\text{Si}(\text{OH})_3$ , has a deteriorating effect upon the quality of the cement. The composition of the hydrated silicate contained in set cement, which Le Chatelier takes to be  $\text{CaSiO}_3 \cdot 2\frac{1}{2}\text{H}_2\text{O}$  or  $2\text{CaSiO}_3 \cdot 5\text{H}_2\text{O}$  can only be correctly expressed by the formula—

It is in fact a hydrated ortho-silicate, to which is linked one molecule of hydrosilicic acid. This bears out W. Michaelis' theory, according to which the cause of the hardening of cement is to be found in the combination of the free hydrated silicic acid with free calcium hydroxide present.—F. M.

*The Calculation of the Fusibility of Clays.* H. A. Wheeler. *Eng. and Mining J.* 1894, 224.

IN connection with the investigation of the clays of Missouri, a large amount of experimental work has been done for determining their fusibilities and other properties. The following considerations are the outcome of this work:—

Bischof, in his "Feuerfesten Thone" (p. 71), gives a formula for calculating the fusibility of a fireclay from a chemical analysis, which is based on the statements that the pyrometric value depends on:—

1. The relation of the alumina to the fluxes (or detrimental).
2. The relation of the alumina to the silica.

From this he derives the following expression for representing what he calls the "Feuerfestigkeitsquotient," or fusibility quotient:—

$$\text{F.Q.} = \frac{\text{Alumina} \times \text{alumina}}{\text{Silica} \times \text{fluxes}}$$

The value of F. Q. he finds to be 14 for the most refractory clays (Saarau, with 1.26 per cent. of detrimental); about 9 for pure kaolins (Zettitz, with 2.00 per cent. of fluxes), 4 for Belgian fireclays (3.0 per cent. of fluxes), and 1 or less for the Rhine fireclays, which have 4 to 7 per cent. of detrimental. From Bischof's statement it follows that the more aluminous a clay is, the more refractory it will be, while the more siliceous or the more impure with detrimental, the less refractory it will be.

Whilst much alumina is indicative of purity in a clay, yet the work on Missouri clays shows no loss in refractoriness when the alumina is replaced by sand, or the clay is very siliceous, whilst every increase in the detrimental decidedly affects the fusibility, especially if the increase is in the alkalis. But the work on the Missouri clays shows that density and fineness of grain have also a very important influence on the refractoriness, and these must be considered in assessing the value of the detrimental present in a clay. Hence Bischof's formula will be totally unreliable, even in clays of similar density and fineness, on account of confusing the silica and alumina as such vital factors of fusibility, when it is mainly, if not entirely, a question of fusible impurities, density, and fineness. When clays are similar in density, and fineness, the refractoriness will be inversely as the detrimental impurities, when the latter are stated in an equation so as to exhibit their proper fluxing values, and if the expression be called the "Fusibility factor," it may be set forth in the following formula:—

$$\begin{array}{c} (\text{A.}) \\ \text{F.F.} = \frac{\text{N}}{\text{D} \times \text{D}'} \end{array}$$

where N represents the sum of the non-detrimental or total silica, alumina, titanic acid, water, moisture, and carbonic acid; D represents the sum of the detrimental impurities, or the iron (as sesquioxide), lime, magnesia, alkalis, sulphuric acid, sulphur, &c.; D' represents the sum of the alkalis, which have been found to have about double the fluxing value of the other fluxes; ferrous oxide is probably about as objectionable, but since it usually oxidises into the less fusible form of sesquioxide in the operation of burning the clay, it is not thus accentuated in ordinary coarse

clays. This formula will be found to give a fairly good comparative value of the refractoriness of clays that do not differ more than 0.2 from one another (the closer the specific gravity the more reliable the comparison) in density, and are of similar fineness of grain. When the clays to be compared differ in density and fineness, then it is necessary to modify formula A by a constant C, that will have different values depending on the density and fineness, so the formula will be—

$$(B.) \\ F.F. = \frac{N}{D \times D' \times C}$$

in which N, D, and D' will have the same values as in formula A; C = 1 when the clay is coarse grained and specific gravity exceeds 2.25; C = 2 when clay is coarse grained and specific gravity ranges from 2.00 to 2.25; C = 3 when it ranges from 1.75 to 2.00; C = 2 when the clay is fine grained and specific gravity over 2.25; C = 3 when it ranges from 2.00 to 2.25; and C = 4 when it is from 1.75 to 2.25. These values of C are only crudely approximate. Sufficient work has been done to show that formula B is the only one that can be used indiscriminately on all kinds of clay, though a very large amount of work has still to be done to arrive at more reliable values for C and the fineness, as the large number of factors involved, makes it a very complex question.

In the table of analyses given herewith examples have been selected from the 110 samples of the Missouri clays that have been completely studied, which fairly illustrate the unreliability of Bischof's formula, the quite satisfactory comparative values given by formula A on clays that are physically similar, and the much more general scope of formula B, which considers physical as well as chemical influences, though it also shows the need of further work to obtain more reliable values for the constant C. Thus, in the St. Louis fireclays, which are all obtained from the same seam, Bischof's formula gives about equal values (1.23 to 1.44) to clays of very different fusibility, and very different values (1.08 to 3.44) to clays of about equal fusibility; the Cape Girardeau kaolin (91.05 per cent. SiO<sub>2</sub> and 1.27 per cent. fluxes) is given a very inferior value for its refractoriness (0.2), though (as the analysis would indicate) it could not be affected by the highest heat of the furnace, while the easily-fusible Winona kaolin is given a higher value (1.5). Again, the Clapper (potter's) clay, which is one of the most, if not the most, refractory clay known, is assigned a value of only 3.7 by Bischof's rule, while the readily fusible Owen-ville fireclay has a value of 4. A further study of the table will show the utter unreliability of Bischof's F.F. as a means of arriving at the relative fusibility of clays.

The table shows that the value of F.F. should exceed 12 when calculated by formula A for coarse, very dense clays, or exceed 10 when using B, for a refractory clay; and the

higher the value the more refractory it will be. It should be remembered in consulting the table that no matter how reliable a pyrometer may be—and the best of them need much care and attention—it is difficult to determine precisely what the temperature of a clay is, when it begins to change, on account of its very poor conductivity of heat; differences of over 100° F. were found within less than half an inch on the same bricklet. In burning a clay, it slowly shrinks and becomes harder as the temperature is raised above a red heat (when it begins to lose its chemically combined water), and at a certain point the granular structure of the raw clay can no longer be distinguished, and it is now found to have a hardness of 6.0 to 6.5; this is called the point of incipient vitrification (in the table), or fusibility, and it is necessary to burn clay wares to this point to develop

strength and hardness. If the temperature be raised still higher, it will become slightly harder, or 6.5 to 7.0, and at a certain point will look more or less stony or vitreous, which is called completely vitrified; at this point the clay will not soften or flow or become distorted. If the heat be still further raised the clay will finally soften, vesicles and bubbles will begin to appear as the result of gases given off by the chemical changes that now slowly take place, and finally a very spongy, scoriaceous, pasty mass will result, unless the heat be raised so high as to thinly liquefy the mass, when the gases escape and melted glass results. The first appearance of the bubbles is called the point of scoriaceous vitrification, or fusion, and shows that the clay is failing and would slowly flow or yield under pressure or abrasion. As the range in temperature is usually

from 300 to 60° F. between this first or incipient point and last or scoriaceous or falling point, with a gradual transition from one to the other, it is difficult to state with any degree of accuracy just when the clay falls, and to decide any closer than a rough approximation as to when a clay gradually passes through the above three important stages in its very slow transition from a rigid solid to a very viscous liquid. Hence the pyrometric determination of these three conditions is only approximate, and an error of 25 to 50° in the figures given in the table is quite possible.

Le Chatelier's thermo-electric pyrometer was used in making the temperature observations, which was calibrated to show changes of 25° F., and the samples, varying from  $\frac{1}{2}$  in. by 1 in. by 4 in. to 1 in. by 1 in. by 4 in. were burned in muffle and graphite crucibles that were run at different degrees of heat in coke-fired assay furnaces.

## X.—METALLURGY.

*The Condition of Gold in Quartz and Calcite Veins.* A. Liversidge. A paper read before the Roy. Soc. of New South Wales, September 6, 1893, 13—17.

GOLD occurring in a soft matrix is often distinctly crystallised, as also when it has been formed in a cavity whatever the nature of the veinstone. But the gold contained in massive quartz as a rule is not crystallised, as may be seen by dissolving the silica away by hydrofluoric acid.

—J. H. C.

*On the Origin of Gold Nuggets.* A. Liversidge. A paper read before the Roy. Soc. of New South Wales, September 6, 1893, 17—57.

THE author gives a summary of the various theories which have been put forth to account for the existence of alluvial gold other than "the old and accepted one," that it has been set free by processes of disintegration. After quoting largely from the writings of Simpson, Davison, C. S. Wilkinson, T. Cosmo Newbery, W. Skey, Brough Smyth, Professor Whitney, Professor Fgleston, and others, he gives detail of a large number of experiments made with a view to determine whether a nucleus of gold immersed in a gold-solution and in the presence of such substances as would be likely to occur in nature will increase in weight, and he concludes that gold is deposited when the nucleus is in contact not only with metalliferous sulphides and arsenides which form strong galvanic couples, but also with such substances as iron oxides, charcoal, graphite, sandstone, granite, quartz, clay, and marble, which form but weak galvanic couples with the gold nucleus. He questions whether the common assertion as to the greater fineness of nugget as compared with coarse vein gold has any foundation in fact. With fine alluvial gold there is such a difference, but this he thinks results from the removal of silver and other impurities by solution owing to the larger relative surfaces exposed.

Discussing the question of solutions of gold in natural waters, he concludes that gold is present in meteoric and mine waters (although absolute chemical proof is still wanting) because it is found in recently-formed pyrites, &c., where it must have come from solution. (E. Sonstadt has demonstrated its presence in sea-water.) Furthermore, the author urges that large nuggets could be artificially produced by following the methods used in his experiments, and believes that gold is probably being so deposited at the present day. However, he does not believe that the large nuggets have thus been formed *in situ*, although gold grains and dust may have been appreciably thus enlarged.

—J. H. C.

*Formation of Cast Iron in Zinc Muffles.* E. Jensch. Chem. Zeit. 1894, 7, 101—102.

A mass of ferruginous regulus was found in the residues contained in a zinc retort, weighing more than a kilo. after removal of cinder and clinker, &c. The temperature to which the retort had been exposed did not exceed 1,500° C. The mass contained several per cent. of sulphur, 1—2 per cent. of silicon, about as much graphite, and 84—87 per cent. of iron, the composition not being uniform throughout; hence it was essentially a mixture of pig iron with iron sulphide and oxide.—C. R. A. W.

*The Principal Smelting Reactions of Blast Furnace Slag, considered on Thermo-Chemical Principles.* A. D. Elbers. Eng. and Mining J. 1894, 297—298.

THE formation of blast furnace slag, the by-product of pig iron, begins after the charges have descended to the furnace zone in which the carbonate of lime changes to free lime, when partially reduced oxide of iron and portions of the lime unite with silica and with silicates by fritting or incipient fusion. Descending through the zone of carburisation, the fritting ingredients contract gradually to sintered or semi-vitrified masses, which even carbonic oxide gas (CO) cannot easily penetrate. In these impervious masses considerable portions of partially reduced oxide of iron remain inclosed until the impervious shell or covering melts off; hence the iron ore does not become completely reduced until it arrives at the zone of fusion.

Further down in the zone of carburisation, the descending charges come in contact with the sulphurous gases that arise from the zone of fusion and from the zone of combustion. "As these gases (chiefly SO<sub>2</sub>) become reduced, sulphides form; the greater portion of the regenerated sulphur combining either with metallic iron or with lime." The lime reaction may be supposed to be the same as when sulphur and lime are heated under exclusion of air in a crucible, viz.,  $4\text{CaO} + 4\text{S} = 3\text{CaS} + \text{CaSO}_4$ . When the temperature of the reducing gases is sufficiently high, a part of the regenerated sulphur is apt to combine with glowing carbon to carbon bisulphide, which can also react on the lime ( $2\text{CaO} + \text{CS}_2 = 2\text{CaS} + \text{CO}_2$ ). Both lime reactions require, however, a higher temperature than the formation of ferrous sulphides does ( $\text{Fe} + \text{S} = \text{FeS}$ ). Hence the formation of sulphide of calcium rises with the temperature of the zone of carburisation, whereas the formation of ferrous sulphide increases when that temperature is not high enough for the formation of sulphide of calcium. Later on, still uncombined portions of the lime unite with the ash of the coal or coke, which consists chiefly of aluminous silicates intermixed with spent pyrites. The latter, at the temperature then obtaining, give off more sulphur and pass into the hearth as ferrous sulphide, excepting such minor portions as may become decomposed by coming in contact with sulphates. After collecting in the hearth, the sulphide of lime remains with the slag, whereas the ferrous sulphide—on account of its higher specific gravity—goes into the metal. When the metal is highly carburised and highly superheated, then the ferrous sulphide is apt to become decomposed by the carbon of the metal ( $\text{FeC} + 2[\text{FeS}] = 6\text{Fe} + \text{CS}_2$ ), and the resulting carbon disulphide is apt to become oxidised in passing upward through the zone of combustion, thus furnishing additional supplies of SO<sub>2</sub> for the regeneration of sulphur vapours in the zone of carburisation.

The flushed or tapped slag is apt to contain more or less of accidental ingredients that had not time to separate from it, such as ferrous sulphide, ferrous sulphate, and agglutinated particles, consisting chiefly of unreduced or partially reduced ore intermixed with carburised metal. When the hardened slag is remelted in a cupola furnace, the greater portion of this accidental ferruginous matter is apt to combine with the silicate masses.

Returning to the reactions that lead to the ultimate combination of the fritting ingredients of the descending charges, their progress can be explained as follows, beginning with the formation of simple silicates by the direct union of their constituent oxides: Nearly all of these oxides are, practically, infusible. The specific heat of those that has been

determined is, approximately, in inverse proportion to their molecular or atomic weight. Then absolute fusibility may be assumed to be in inverse proportion—and their absolute melting point, consequently, in direct proportion—to their specific heat. Their actual melting behaviour depends, however, to some extent, on the state of their molecular condensation. Magnesium oxide, for instance, is more fusible than calcium oxide, though its specific heat is considerably higher than that of calcium oxide can be assumed to be. These deviations from the general rule have, however, no practical bearing on the igneous reactions of the respective substances, inasmuch as calcium oxide fuses, with silica, at a lower temperature than magnesium oxide does, and their contingent melting point may, therefore, be assumed as approximately proportionate to their specific heat.

Adopting the latter conclusion as a general rule, the comparative or contingent fusibility of the more important constituents may be assumed to stand in the following order, beginning with the oxide having the lowest specific heat, and consequently the lowest melting point:—

As FeO does not occur in the free state, its specific heat as well as its contingent fusibility have to be inferred from those of  $\text{Fe}_3\text{O}_4$ . According to general rules  $\text{Fe}_3\text{O}_4$  must be more fusible than  $\text{Fe}_2\text{O}_3$ , and FeO more fusible than MnO. That the melting point of rhodonite ( $\text{MnO}, \text{SiO}_2$ ) is considerably lower than that of fayalite ( $2\text{FeOSiO}_3$ ) can only be due to the greater condensation of the ferrous silicate-molecules, inasmuch as the condensation of like molecules ( $2\text{FeOSiO}_2 + 2\text{FeOSiO}_2$ ) involves the absorption of heat, and consequently a proportionate increase in the molecular heat, and a corresponding diminution in the fusibility of the condensed compound.

The primary fritting reactions may be defined as "the chemical combination, of molecules of two unlike substances, at a temperature that is below the melting point of either substance." As their mass becomes heated the respective substances accumulate energy according to their specific heat, the one having the higher specific heat accumulating, proportionately, more of it than the other. The excess of the energy that accumulates in the particles of the substance having the higher specific heat is proportionate to the difference in the molecular heat of the two, and can be transmitted by contact. Molecules of silicic oxide and molecules of a basic oxide unite thus, on the surfaces of contact of the respective particles, and in definite proportions, to primary silicate-molecules. As already stated, the amount of the energy that is set free by their union must be proportionate to the difference in their molecular heat, but it must also be larger than the amount of the excess that accumulated in the substance having the greater specific heat of the two, inasmuch as they combine at a temperature that is below the melting point of either of them. Hence, the specific heat of a primary silicate-molecule must be lower than that of either of its constituent oxides.

But the melting point of the most easily fusible simple silicates, of the alkalis, oxide of lead, &c., is higher than that of the respective basic oxides, whereas the melting point of a natural simple silicate of lime (Wollastonite) is considerably lower than that of its base, which is practically infusible. This seeming inconsistency can only be accounted for by assuming that the melted molecules unite, primarily, in the proportions of an equal oxygen ratio ( $2\text{CaO} + \text{SiO}_2, 2\text{Al}_2\text{O}_3 + 3\text{SiO}_2$ , &c.), inasmuch as the total amount of the energy that is set free, when the respective molecules combine in the proportion of 2:1 or 2:3, is greater than that which could be set free if they combined in equal numbers. Moreover, if they combined in the latter proportion,  $\text{CaO} + 2\text{SiO}_2$  would be more fusible than  $\text{CaO} + \text{SiO}_2$ , inasmuch as the specific heat of  $\text{SiO}_2$  is lower than that of  $\text{CaO}$ ; and if the specific heat of  $\text{CaO}$  were lower than that of  $\text{SiO}_2$ , then  $2\text{CaO} + \text{SiO}_2$  would be more fusible than  $\text{CaO} + \text{SiO}_2$ , which is not in accordance with the well-known melting behaviour of mixtures having their constituents in the respective proportions.

If, on the other hand, it be assumed that the primary silicate molecules are single silicate molecules ( $2\text{CaOSiO}_2$ , &c.), then the thermal properties of all silicates, whether artificial or natural, can be accounted for in conformity with thermo-chemical rules. According to these rules the secondary reactions of the combining oxides must then progress in the following order:—

As the fritting temperature rises, the primary silicate-molecules that have formed at the initial temperature recombine, at first, with molecules of the oxide having the lower specific heat of the respective constituents, and, in thus recombining, energy is again set free under evolution of heat. The amount of energy that is thus liberated decreases as the measure of the absorption increases ( $2\text{CaOSiO}_2 + \text{SiO}_2$ , &c.); and when it falls short of the amount that is required for the molecular work of recombination, then no further reactions can take place at the temperature obtaining, inasmuch as additional energy can only be accumulated with advancing temperature.

As the fritting heat becomes more intense, the more refractory of the basic oxides unite, with silica, to primary silicate-molecules, whereas the primary silicate-molecules that have formed at the lower temperature begin to take up molecules of the basic oxides, the specific heat of which is higher than that of the silica; and the simple silicate-molecules combine then to compound silicate-molecules, viz.:—

The latter mode of combination must also be that by which the aluminous silicates of the ore and coal unite with basic oxides, viz.:— $\text{Al}_2\text{O}_3, 2\text{SiO}_2$  ( $\text{Si}_2\text{Al}_2\text{O}_5$ ) +  $\text{CaO} = \text{CaOAl}_2\text{O}_5, 2\text{SiO}_2 = \frac{1}{2}(2\text{CaOSiO}_2) + \frac{1}{2}(2\text{Al}_2\text{O}_3, 3\text{SiO}_2)$ .

From the melting behaviour of natural silicates that have the same constituents as blast-furnace slag, it may be inferred:—

1. That the specific heat of simple silicates is, approximately, proportionate to the specific heat of their constituent oxides.

2. That the specific heat of compound silicates is, approximately, proportionate to the specific heat of their constituent simple silicates.

Applying these deductions to the melting reactions of the fritting ingredients, the following conclusions are arrived at:—

1. As the specific heat of  $\text{CaO}$  is higher than that of  $\text{SiO}_2$ , the melting down of a charge, having the respective constituents in single-silicate proportions, requires a higher temperature than the fusion of a corresponding bisilicate composition.

2. A charge that is high in alumina melts more rapidly than a charge that is low in alumina, because the specific heat of compound silicates of lime and alumina is lower than that of simple silicates of lime ( $\text{CaO}$ ) of corresponding constitution.

3. As the specific heat of magnesium oxide is higher than that of alumina, the compound silicates of lime and magnesia do not melt as readily as the compound silicates of lime and alumina.

From the melting behaviour of hardened slag, and from that of other compounds that consist of amorphous mixtures of silicates, such as glass, it must, however, be inferred that the specific heat of such mixtures is, again, approximately proportionate to the specific heat of their constituent oxides. In other words, the molecular heat of the simple silicate-molecules is lower than the sum of the molecular heat of their constituent oxides, and the molecular heat of the compound silicate-molecules is lower than the sum of the molecular heat of their constituent simple silicates; but the molecular rearrangements that take place when unlike compound silicate molecules unite, absorb just as much energy as was set free by their formation.

Hence, though compound silicates of lime and alumina melt more readily than simple silicates of lime, the formation of a homogeneous slag requires a higher temperature

when the contents of alumina are high than when they are low, inasmuch as the specific heat of  $Al_2O_3$  is higher than that of  $CaO$ .

It further follows that not all unlike silicates can combine with each other.

As the tritted masses melt and trickle down into the hearth, intimately intermixed with carburised metal, their ferruginous constituents become gradually reduced, and the reduction continues after they have collected in the hearth, because carburised metal passes continually through the collected silicate masses.

The progress of the respective reactions may be illustrated as follows:—

The amount of energy that is absorbed by the reduction of the silicates of iron—as above indicated—is considerably larger than that which is set free by the formation of the resulting silicides of iron (which go, of course, into the metal, where they are apt to become reoxidised by particles of unreduced ore unless the metal is high in carbon). The complete reduction of the ferruginous constituents of the slag is, therefore, only possible when the temperature of the hearth is very high and when the metal is highly carburised. But when the furnace is working well, then the temperature of the furnace is also proportionate to the fusibility of the charges. Hence the reduction of the ferruginous constituents is, practically, proportionate to the specific heat of the collected silicate masses.

The charges that are fluxed with dolomitic limestone are usually lower in alumina than the charges that are fluxed with calcite ( $CaCO_3$ ); and the specific heat of the magnesian slag that is low in alumina is higher than that of the calcareous slag that is high in alumina.

The specific heat is also lowered by an increase in the proportion of the silica; hence—as regards ultimate results—it may be said that the contents of the ferruginous constituents increase in a measure with the acidity of the slag; and for slag of the same silicate constitution: 1. That in calcareous slag the proportion of their contents is approximately in inverse proportion to the contents of alumina; 2. That in magnesian slag the proportion of their contents rises in a measure with the proportion of the alumina.

The writer has found that blast-furnace slag of the magnesian type is practically free from combined iron (in contradistinction to the mechanical admixtures heretofore mentioned) when it is approximately of single-silicate constitution, and when the contents of alumina do not exceed the proportion indicated by the molecular formula:  $12(Ca, Mg)O, Al_2O_3, 7\frac{1}{2}SiO_2$ , the relative proportions of  $CaO, MgO$ , being: 6—7  $CaO$ , 5—6  $MgO$ . As the reduction of manganous silicate requires a higher temperature than the reduction of ferrous silicate, it may also be said that the reduction of the ferruginous constituents increases in a measure with the contents of manganous oxide.

*The Nickel Industry.* J. H. L. Vogt. Stahl und Eisen, 1894, 14, 23.

With the increasing demand for nickel-steel, a further increase in the production of nickel is to be expected. In 1868 the world's production of nickel was only 700 tons, while this figure increased to 2,500 tons for the year 1890, and in 1891, in consequence of the Canadian output, to 4,500 tons for that year. The Canadian ore contains about 2.65 per cent. of nickel, and as much copper; the Norwegian containing about 2 per cent. of nickel, only a trace of copper, but more cobalt. A ton of ore in Canada costs 20 shillings, so that 1 kilo. of nickel, in the ore, costs 9½d.

The ore is submitted to the following treatment:—(1.) Open roasting. (2.) Fusion in water-cooled blast-furnaces to nickel-matte of 15—16 per cent. Ni and 15 per cent. Cu. (3.) Fusion in converter with blast to 10 per cent. of Ni. (4.) Roasting in reverberatory furnaces. (5.) Chlorinating,

roasting, and extraction of copper as chloride. (6.) Removal of iron by heating in reverberatory furnaces with iron pyrites; the nickel sulphide is then roasted and reduced to metal. The cost, inclusive of ore, amounts to 2s. 5¾d. per kilo. of nickel.

The nickel Bessemer process is carried out at three works in Canada already, and worked very satisfactorily, yet there is much room for improvement. The wealth of Norway in nickel ores, deserves more considerable exploitation, and by good work, such as is attainable through the employment of water-power for refining by electrolysis, nickel may be produced cheaper there than in Canada.—W. B. H.

## PATENTS.

*Processes of Separating Metals Covering Scraps, Clippings or other Pieces of Metal of all kinds.* F. E. de Fursac, J. C. Moisset, and J. B. J. Very of Orléans, France. [Under International Convention.] Eng. Pat. 3583, September 9, 1892.

The apparatus employed consists of one or more receivers having perforated walls grouped around a rotary shaft and permitting the repeated and alternate contact of the metal to be treated with the liquid and with the air. This is illustrated by drawings, but the use of any other apparatus, exposing mechanically, alternately, and completely the surfaces to be treated, is also claimed.—J. H. C.

*Coating Iron and Steel with Brass and other Metallic Alloys.* A. V. C. Fenby, and J. B. Fenby, of Sutton Coldfield, and G. Moore, Erdington, Warwick. Eng. Pat. 1906, January 28, 1893.

The articles to be coated are first thinly coated with copper, zinc, or other suitable metal by any of the ordinary methods, and then dipped in a bath of molten brass or other alloy, which is maintained at a suitable temperature, while its surface is protected by a layer of borax or other flux.

—J. H. C.

*Improvements in or relating to the Treatment of Metallic Ores.* C. G. Richardson and A. B. English, Toronto, Canada. Eng. Pat. 2119, January 31, 1893.

Ores or matters containing nickel or copper, or both combined, are finely ground, and then fused in a suitable furnace with a proper proportion of dehydrated gypsum or other suitable sulphate, so as to remove any iron present in the state of a soluble silicate, and leave the nickel and copper in the state of sulphide. The sulphurous acid given off during the fusion may be used for the preparation of sulphuric acid or such other purpose, as may be desired.

—J. H. C.

*Improvements in the Treatment of Galena for the Production of Lead, Lead Sulphate, and Lead Oxide.* A. Macdonald, London. Eng. Pat. 2883, February 9, 1893.

The galena is melted and treated in a converter by blowing air or oxygen into or upon it, whereby a large proportion of it is driven off as sulphate of lead fume, which may be collected in any known manner, the rest being left as metallic lead.

It is preferred in the first place to charge the converter with molten lead, and to blow air into this, whereby litharge is produced and the temperature is raised, when the galena may be added. In some cases sulphur is added during the blow. Any silver present is concentrated in the last portion of the metallic lead.—J. H. C.

*Improvements relating to the Purification of Metals in their Moulds, and in the Production of Dense and Flawless Castings, and to Apparatus therefor.* E. Taussig, Bohrenfeld, Holstein, Germany. Eng. Pat. 3503, February 16, 1893.

AFTER casting in the ordinary way, the metal is remelted while still in the mould by passing through it a current of electricity, the mould being placed for this purpose in a hermetically closed chamber, while the gases generated are drawn off by means of a fan or vacuum pump, so producing a more or less complete vacuum.—J. H. C.

*Improvements in and relating to the Manufacture of Zinc Oxide.* A. Gray, Glasgow. Eng. Pat. 4310, February 28, 1893.

Waste cuttings of zinc, zinc ashes, skimmings, &c. are burnt with coke in a furnace of the cupola type, having at the base a grating of either solid or hollow furnace bars, through which a blast of air or steam, or of both, is forced from a spiral tube with jets placed under the bars. Sufficient air is supplied to burn the fuel and to oxidise the zinc.

The products of combustion are drawn through a flue into a chamber, where the zinc oxide is collected by the aid of a spray of cold water, by steam, or by other means.

—A. W.

*Improvements in the Treatment of Slimes, or Finely-divided Ore containing Precious Metals.* C. Raleigh, Johannesburg, S. Africa. Eng. Pat. 5163, March 9, 1893.

To prevent settling or packing of the slimes in the process of extracting precious metals by the chlorine, cyanide, or other lixiviating process, any suitable apparatus for pulsating, vibrating, or jiggling the material under treatment by the injection of air, water, or gas is employed. The inlet for injection may be under or over the filter bed, or at the side of the vat, according to the motion required. The leaching solution may take the place of the water jet, and oxygen gas can be used with advantage to accelerate the solution of the gold or silver.

Muddy water or solution may also be used to increase the density of the leaching solution, so as to further prevent the rapid settling of the grains of ore.

The exact method of application depends on the kind of material under treatment.—A. W.

*An Improved Process for Coating or Plating Non-metallic Articles with Metal.* T. M. Ash, H. W. Gill, and L. Green, Birmingham. Eng. Pat. 5327, March 11, 1893.

ARTICLES such as paper, papier-maché, and other fibrous or textile articles, as well as leaves of plants or other natural objects, are covered with a varnish or other adhesive compound not soluble in water, with which copper or tin have been intimately mixed in a minutely divided state. After washing or partial drying the articles are immersed in a bath of nitrate of silver or other metallic bath until sufficiently coated. Or, if preferred, the object to be treated may be varnished and dusted over with the finely-divided metal before immersion in the silver bath.—J. H. C.

*Improvements in or relating to the "Thomas" Metallurgical Process.* H. Wild, Peine, Germany. Eng. Pat. 6219, March 23, 1893.

This patent refers to the duration of the overblow in the "Thomas" process. As a rule the bath is too much blown, whereby too much iron oxide is formed in the slag and rephosphorisation of the metal takes place. To remedy this the process is carried out as follows:—The first charge is blown in the manner hitherto practised; the necessary qualitative and quantitative tests are previously taken; the carbon, phosphorus, and manganese in the finished product are severally determined and the Thomas slag is analysed in regard to its proportion of iron. On the supposition that the quality of the finished product is satisfactory, comparison is made of the proportion of iron contained in these several slags with each other, and should they be found to differ, the attempt must be made still further to reduce the lowest proportion found by a reduction of the time of overblow. It is maintained that by the shorter duration of overblow there is a reduction of the waste, a smaller consumption of lime, spiegel, &c., a more even quality of metal, and a more valuable slag.—A. W.

*An Improved Process for the Utilisation of Old Articles of Tin Plate, such as Boxes, Cansisters, and the like.* A. Gutensohn, London. Eng. Pat. 6238, March 23, 1893.

THE old tins are first sorted and those with solder joints are heated in pots in a furnace to remove the solder. If the remaining pieces of tin plate are sufficiently large they are cleaned by soda, lime, or other cleaning material, and are re-tinned and passed through finishing rollers. The small pieces which cannot be again made into tin plate are freed from their coating of tin by any known method and used as scrap iron.—A. W.

*A New or Improved Process for Recovering Zinc or Spelter from Waste Galvanised Iron or Steel, and Furnaces and Appliances for the said Process.* W. Hayward, Wolverhampton. Eng. Pat. 7252, April 8, 1893.

THE waste is heated to a temperature somewhat higher than the melting point of zinc in closed or partially closed heating chambers, by which means the zinc is melted off and runs through a hole in the floor of the chamber into an open receptacle or into a vessel of water. The chamber preferred is a kind of reverberatory furnace.—J. H. C.

*Improvements in the Manufacture of Iron and Steel.* A. Sattmann and A. Homatsch, Donawitz, Austro-Hungary. Eng. Pat. 8057, April 21, 1893.

IN the specification, furnaces are described of special construction, for the carrying on, either continuously or intermittently, of the manufacture in all its stages of definitely carburised iron, from its ore. Gaseous fuel is used for heating the ores and fluxes, and for reducing and carburising the spongy iron, solid fuel for melting the spongy iron, and oxidising gases for refining the molten

carburised iron after separating the slag. These fuels are introduced through nozzles and doors according to the local requirements of the furnace. Various ways in which this can be done are described, the furnace being of the blast-furnace type with the additions near or below the bed.

—A. W.

*An Improved Amalgamating Apparatus, to be Employed either Alone or in Combination with Concentrating Apparatus or Buddles.* W. A. Green, Aberystwyth. Eng. Pat. 11,182, June 7, 1893.

In amalgamators of the circular pan and revolving muller type the pan is lined with copper, to the surface of which the mercury adheres, instead of as heretofore being entirely constructed of iron. The object of this is to prevent any of the ore creeping between the surface of the pan and the underside of the layer of mercury therein, thus escaping proper amalgamation by the action of the muller. Furthermore, instead of making the muller with a flat surface for acting upon the ore and mercury, such surface is made with a spiral rib so that as the muller revolves it causes the ore, which is fed through a central opening in it, to be slowly advanced from the centre to the outer circumference of the pan.—A. W.

*Process and Apparatus for the Extraction of Zinc.* L. V. T. Lynen, London. Eng. Pat. 16,180, August 28, 1893.

The retorts used are all connected to one or more common condensing chambers, by which means a proper regulation of temperature is facilitated. The furnace is entirely closed so that no escape of zinc vapour takes place. The retorts are mechanically charged, combustible envelopes being used for each charge to facilitate this.—J. H. C.

*Improved Means Applicable for Use in Extracting Gold and Silver from Auriferous and Argentiferous Solutions.* C. Raleigh, Johannesburg. Eng. Pat. 23,241, December 5, 1893.

The solutions are filtered through granular or permeable electrodes, which act in conjunction with a current of electricity to decompose the solutions in their passage. The precious metals are precipitated and deposited in the interstices of the filtering material, and the resultant solutions are used for lixiviating a fresh charge of ore. The electrodes are composed of fragments of loose or compressed charcoal, carbon, metal, metallic alloys, or amalgams. The precipitation may be expedited when necessary by artificial heat and the introduction of air, oxygen, or hydrogen, and either with increased or reduced pressure.—J. H. C.

*Improvements in Methods of Casting Solid Ingots of Steel.* W. P. B. Urlick, Newark, U.S.A. Eng. Pat. 23,425, December 5, 1893.

The patentee states that the hollowness of the upper end of steel castings is due to gases in the metal, evolved during the cooling process, being imprisoned by the hardened shell which first forms at the head of the metal. He overcomes this by introducing, at a suitable moment, when the metal is neither too fluid nor too pasty, a rod into the upper end of the ingot, whereby a cavity is formed which allows the gases to escape. This cavity is then filled up by pouring into it molten steel, which unites with the remainder and forms a homogeneous whole.—A. W.

*Improvements in Furnaces for Distilling Zinc, Cadmium, and the like.* F. W. Golby, London. From C. Fraenkel, of Schweidnitz, Prussia. Eng. Pat. 23,979, December 13, 1893.

In these furnaces magnesite is used instead of fire-clay for the retorts. The magnesite is formed into bricks of a peculiar shape, and of these bricks the retorts are built up. The heating is effected by the gases produced in a generator.—J. H. C.

*An Improved Process of Removing Tin from Tin Scrap or Tin-coated Metal.* T. G. Hunter, Philadelphia, U.S.A. Eng. Pat. 132, January 2, 1894.

The tin scrap is placed in a grate or basket of gun-metal or other suitable material, which is suspended in a tank, heat being applied by means of steam when necessary. The scrap is then treated with a neutral solution of sulphate of copper or other suitable sulphate until all the tin is separated in metallic form; metallic copper is also formed, and both metals fall to the bottom of the tank, together with small quantities of minor impurities. The bulk of the iron remains in the basket, and may be removed as required. The solution of sulphate of iron formed in the operation is drawn off and the mixed metallic copper, metallic tin, and other substances present are utilised in any way known to the arts.—J. H. C.

*Improvements in the Treatment of Zinc-Lead-Sulphide. Ores Carrying Gold or Silver, or Gold and Silver.* J. C. Fell, London. From The Emmens Zinc Company, New York, U.S.A. Eng. Pat. 2041, January 30, 1894.

The object of this patent is to remove the zinc existing in refractory ores containing lead, gold, or silver. The ore is crushed, roasted in an oxidising atmosphere to dull redness to convert the metallic contents to sulphates and oxides, after which the roasted material is finely pulverised and leached with water containing about 1 per cent. of ferrous sulphate. This leaching extracts the zinc sulphate present in the ore, and the ferrous sulphate precipitates any silver that may be dissolved.

The ore is then leached with a solution of ferric sulphate, containing a little ferrous sulphate, which dissolves and removes any zinc that may be left by the first leaching in the state of oxide or sulphide. The residue is again leached with water containing ferrous sulphate to wash out any liquid remaining from the second leaching, and is then a finished concentrate containing the whole of the original lead, silver, and gold. The zinc may be recovered from the liquors by crystallisation or any other convenient means.—A. W.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

*Silicon Carbide ("Carborundum").* O. Mühlhäuser. Zeits. ang. Chem. 1893, 637—646.

ACHESON discovered (this Journal, 1893, 847) that when a mixture of silica and carbon is heated to a high temperature in the electric furnace, carbon monoxide is evolved and a carbide of silicon produced. The reaction has been studied a little more in detail by the author. The mixture, which is placed in the electric furnace, contains powdered coke 100 kilos., Millington sand 100 kilos., and common salt 25 kilos. The function of the salt is purely a mechanical one. After the operation is over it cements the sand and coke particles together, and so facilitates the separation of the crystalline "carborundum." Some of the impurities in the raw materials, such as iron, calcium, magnesium, &c., are also converted into carbides; and the purer the raw materials, the more nearly colourless are the crystals of silicon carbide. There is formed at the same time a small quantity of amorphous carborundum just above the zone in which the crystalline compound is obtained.

As regards their hardness, the crystals lie between sapphire and diamond, and in the scale of hardness have the value 9.5. Used in connection with a polishing wheel, carborundum is able to cut holes in the hardest steel, and it is stated that the temper of the steel is in no wise destroyed. As an abrasive it can do the same work as corundum, in one-third to one-fourth of the time.

In order to determine the composition of carborundum, the crystals were ground up in a steel mortar and subsequently in an agate mortar, and then submitted to the

process of elutriation. In order to get samples for silicon determinations it is sufficient to allow the substance to settle for one minute before decanting. For carbon determinations, however, the carbide must be very finely divided, and for this purpose five minutes' settling are necessary. The carbide cannot be burned in oxygen, but it is readily oxidised by igniting with lead chromate. The composition of the carboreundum so obtained is given in the following table:—

	I.	II.	III.
Si.....	62.70	62.21	61.59
C.....	36.26	36.35	34.47
Al <sub>2</sub> O <sub>3</sub> and Fe <sub>2</sub> O.....	0.93	1.33	0.53
CaO.....	0.00	0.00	0.35
MgO.....	0.11	0.12	0.06

Pure silicon carbide may be obtained by igniting the very finely-divided crude material in oxygen, boiling out with caustic potash (1:3), and then with hydrochloric acid. It is afterwards treated with hydrofluoric acid and thoroughly washed. It then has the composition—

	I.	II.	Calculated.
Si.....	69.19	69.19	70.0
C.....	29.72	30.21	30.0
Al <sub>2</sub> O <sub>3</sub> and Fe <sub>2</sub> O.....	0.38	0.46	..
CaO.....	0.19	0.15	..
MgO.....	0.06	0.00	..

The specific gravity of the pure substance at 15° C. was found to be 3.22. The author has also analysed various products formed during the reaction, and also the gases evolved, and recommends that the carbon monoxide should be burned before allowing it to escape.—J. S.

#### Electrolysis of Alkaline Chlorides. E. Oetzel. Chem. Zeit. 18, 69—70.

THE electro-motive force requisite to decompose sodium chloride in aqueous solution may be reckoned thus, according to Nourrisson:—

Heat absorbed—	
NaCl = Na + Cl.....	— 364 calories.
H <sub>2</sub> O = H <sub>2</sub> + O.....	— 684 „
	— 1,048
Heat evolved—	
Na + O + H + H <sub>2</sub> O.....	+ 1,118 „
Formation of compounds of chlorine and oxygen.....	say + 60 „
	+ 1,178
Net heat absorption.....	— 470

470 calories represent  $\frac{470}{232} = 2.02$  volts.

These figures, however, are open to correction: the heat disturbance due to the formation of hypochlorous and chloric acids is a secondary result, not affecting the primary electrolysis, and is, moreover, of negative sign; in any case it should not be brought into account. The following figures more nearly represent the E.M.F. requisite for the primary decomposition:—

	Gramme Calories.
— (Na, Cl, H <sub>2</sub> O).....	— 96,510
— (H <sub>2</sub> , O).....	— 68,500
+ (Na, O, H, H <sub>2</sub> O).....	+ 111,510
Sum.....	— 53,000

53,000 gramme calories represent  $\frac{53,000}{23.067} = 2.30$  volts.

Values of 2.25–2.28 volts were obtained by the author as the actual potential difference subsisting between gas carbon electrodes whilst electrolysing common salt solution with a porous earthenware diaphragm, using currents varying between 3 and 60 amperes; practically the same values are found with potassium chloride solution. As the action goes on, caustic soda (or potash) solution accumulates round the cathode, and brine saturated with chlorine round the anode; these two liquids tend to intermix by diffusion through the porous septum, so that more or less hypochlorite is formed. This, in the neighbourhood of the cathode, acts as a “depolariser,” becoming reduced to chloride; but in the vicinity of the anode a different result is brought about, the hypochlorite being partially oxidised to chlorate and partially electrolysed directly, with production of caustic soda and hydrogen at the cathode as before, and of hypochlorous acid and oxygen at the anode. In similar fashion the chlorate produced by oxidation of the hypochlorite partly diffuses to the cathode and is there reduced, and partly becomes electrolysed, evolving at the anode chloric acid and oxygen. On the whole, the more porous the septum, and the more concentrated the caustic soda solution round the cathode, the greater the production of oxygen compounds of chlorine.

The gas evolved is never pure chlorine, but always a mixture of chlorine and oxygen. The latter is usually attributed to the electrolysis of hypochlorite, but is also due to (and probably principally caused by) the direct electrolysis of the caustic soda solution first formed, this becoming decomposed into sodium, hydrogen, and oxygen, just as the sodium chloride is split up into sodium and chlorine. The sodium thus eliminated at the cathode necessarily acts upon water there, reproducing caustic soda; so that the caustics tending towards the evolution of oxygen instead of chlorine are continually increasing in magnitude. The particular fraction of the total current which at any given moment electrolyses caustic soda rather than sodium chloride, depends on the relative richness of the solution in these compounds respectively; for equal concentrations the conductivity of caustic soda solution is greater than that of brine; moreover, the E.M.F. requisite to electrolyse caustic soda solution is only 1.5 volts, or 0.8 volt less than that requisite for sodium chloride. When the chlorides of the metals of the alkaline earths (lime and magnesia) are electrolysed, the lime (or magnesia) formed at the cathode is comparatively insoluble, and consequently is not electrolysed in the way that caustic soda solution is decomposed; accordingly the chlorine evolved is practically free from oxygen. On the other hand, when sodium sulphate is electrolysed, sulphuric acid is formed at one electrode and caustic soda at the other, both of which substances are good electrolytic conductors; so that the work of the current is divided between the three substances, original sulphate, sulphuric acid, and caustic soda.

—C. R. A. W.

#### PATENTS.

##### Improvements relating to the Extraction of Metals by Means of Electricity, and to Apparatus therefor. E. Taussig, Bahrenfeld, Holstein, Germany. Eng. Pat. 3573, February 17, 1893.

THE inventor describes an arrangement in which the electric furnace, provided with electrodes of large size, is enclosed in a case which can be kept exhausted during the working process.

The moulds, into which the metal obtained is to be cast, are also exhausted during the running of the metal.

It is claimed that the metal obtained is purer, some of the impurities usually present when non-exhausted furnaces are employed being withdrawn by the pumps while in a gaseous state; and further, that the addition of fluxes, carbon, &c., is in most cases superfluous.—E. T.

*Improvements in the Electrolytical Decomposition of Chlorides and Mixtures thereof, and in Apparatus for the Purpose.* F. M. Lyte, London. Eng. Pat. 7591, April 13, 1893.

This invention is illustrated by a description of the arrangements suitable for the electrolysis of lead chloride. In a vessel of suitable mechanical strength, but not of chlorine-proof material, is melted a sufficient quantity of lead by means of a furnace arranged below. An inverted bell of some material that must be chlorine-proof, but which, as it has to withstand no great pressure, need not be mechanically strong, is placed so that its rim is some way below the surface of the molten lead. A tube passes through the top of the bell nearly to the surface of the lead, and serves for the introduction of lead chloride to form a fairly deep layer above the metal. The current is passed into the apparatus by carbon anodes dipping into the fused chloride, the molten lead forming the cathode. The metal reduced flows away by a suitable hot overflow pipe; the chlorine is led away by a pipe at the top of the bell.

The anodes are rods with a hole passing in each, from the top nearly to the bottom. In this is placed an easily-fusible metal—such as lead—which, remaining molten during the action of the furnace, makes good contact both with the carbon and with a metal rod attached to a terminal, and dipping into it. In some cases a split springy tube replaces the fusible metal. The object is to reduce the electrical resistance.—E. T.

*Improvements in or connected with Cells for Electric Batteries.* H. C. W. Emery, London. Eng. Pat. 8571, April 28, 1892.

As arrangement for removing the exciting liquid from the electrodes by changing the position of the containing cell.

The electrodes are fixed at one end of the latter, and when in use are vertical and immersed partially in the liquid. By turning the cell on to its side, however, the electrodes rest horizontally above the surface of the liquid, and are therefore preserved from waste during disuse of the cell. A partition can be used, reaching from the top nearly to the bottom, in order to prevent splashing of the liquid—though no arrangements are described for the escape of air from behind the partition.—E. T.

*Improvements in the Manufacture or Production of Soda Crystals.* H. R. Broome, Ross-lea-Lancaster, and M. Guthrie, Liverpool. Eng. Pat. 8907, May 3, 1893.

See under VII., page 394.

*Improvements in Apparatus for the Electrolytic Decomposition of Metallic Salts.* C. Kellner, Vienna, Austria. Eng. Pat. 24,274, December 16, 1893.

ADAPTED for the decomposition of salts where mercury is used as cathode. Below the surface of the electrolyte dips a vessel, which is glazed at the sides, but porous at the bottom. This porous bottom is covered by a thin layer of mercury forming the cathode. The anodes are either at the sides of the semi-porous vessel or are placed below, in which case deflecting vanes are arranged to carry the gas from the neighbourhood of the porous bottom. By this arrangement it is claimed that the mercury is kept from direct contact with the electrolyte; whilst, by keeping a suitable "reaction fluid" above the mercury, any waste of the latter is prevented, the "cation" being yielded up by the mercury directly to this "reaction fluid."—E. T.

*Improvements in Dry Batteries.* H. T. Johnson, New York, U.S.A. Eng. Pat. 24,871, December 27, 1893.

The carbon electrode used in dry batteries is made with a grooved or corrugated surface, and may be perforated or provided with numerous knobs or projections. The object in each case is to prevent loss of contact between the carbon and surrounding material in case of any shrinking or displacement of the latter, and at the same time to prevent the electrode from being easily drawn from the cell in case

of breaking or cracking of the seal. Greater contact surface is of course given at the same time, which is an advantage.—E. T.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

*Oxidation of Fatty Oils.* W. Fahrion. Chem. Zeit. 17, 1848—1850.

IN spite of various researches, the exact nature of the chemical actions taking place when oils "dry" (by the spontaneous oxidation effected by exposure to air in thin films) remains for the most part obscure. Mulder regarded the chief fatty acid of linseed and other drying oils as  $C_{18}H_{32}O_2$ , and considered the effect of "drying" to be that the glyceridic portion became wholly destroyed, whilst the supposed linolic acid,  $C_{18}H_{30}O_2$ , became oxidised, first to linonic acid,  $C_{18}H_{28}O_3$ , and then to a neutral body, linoxyn,  $C_{32}H_{54}O_{11}$ . Hazura and Bauer found the acids of the drying oils to be mixtures in different proportions of oleic acid,  $C_{18}H_{34}O_2$ , linolic acid,  $C_{18}H_{32}O_2$ , linolenic acid,  $C_{18}H_{30}O_2$ , and isolinolenic acid, also  $C_{18}H_{30}O_2$ . Of these the glycerides of the last three are not broken up by the oxidation, whilst the glycerides of saturated acids (such as palmitic, myristic, &c.), when present, are first attacked with destruction of the glyceridic part of the molecule, and liberation of free fatty acids; olein is similarly attacked to some extent, whilst linolin and linolenin take up oxygen without losing glycerol, forming a series of bodies of which the final member is the glyceride of the acid  $C_{18}H_{26}O_7$ , this substance being simultaneously a species of anhydride. The author has investigated the nature of the intermediate products so far as the acids thence obtained by saponification are concerned, the method of experimenting being to increase largely the surface exposed to the air by saturating chamois leather with the oil to be examined; after long continued exposure (in some cases for many months, partly in sunlight,) the leather was cut into fragments and treated with cold ether; the ethereal solution was repeatedly shaken with water to remove nitrogenous matters taken up from the leather and evaporated; the fatty acids obtained on saponifying the residue, were partly soluble, and partly insoluble in petroleum ether, the latter portion consisting of the products of oxidation, the former of unoxidised fatty acids. The oxidised fatty acids were readily soluble in ether, in alcohol, and in aqueous ammonia; from the latter solution fractional precipitation with barium chloride enabled a partial separation to be effected. From the results of combustions and determinations of the "iodine number," &c., of the products so obtained, the conclusions are drawn that linolic acid (cotton seed oil), furnishes a series of oxyacids where successively 1, 2, 3, and 4 atoms of oxygen are added on, forming respectively oxy-, dioxy-, trioxy-, and tetraoxy-linolic acids, the aerial oxidation action going no further than this last. Similarly, linolenic and isolinolenic acids (linseed oil) furnish a parallel series, the final product appearing to be an anhydride of hexoxylinolenic acid,  $C_{18}H_{26}O_7 = C_{18}H_{30}O_6 + H_2O$ , six oxygen atoms being added on; whilst jeconic acid (cod liver oil) gives analogous products, the final one being a double anhydride of pent-oxyjeconic acid,  $C_{18}H_{26}O_5 = C_{18}H_{30}O_4 + 2H_2O$ . As the

addition of oxygen goes on, the acids gradually become more and more solid; the original unoxidised bodies are perfectly fluid, whilst the more oxidised members are completely solid and can be powdered. The solubility in ether decreases as the oxidation progresses, whilst the opposite is the case as regards the solubility of the barium salts in water. The addition of oxygen is mostly of such a character as to form a kind of anhydride, which takes up water under the influence of alkalis, &c.; as oxidation of a glyceride progresses, the glyceridic character of the product is still maintained in the case of unsaturated acids, the original colour of the oil being maintained.—C. R. A. W.

*The Oxidation of the Fatty Oils.* W. F. Allen.  
Chem. Zeit. 17, 1453.

The oxidation of the fatty oils by the atmospheric oxygen is a very slow process, which, however, can be considerably hastened by exposing them in a very fine state of subdivision. For this purpose Vogel impregnated cotton with the oil, but the author suggests soft, porous leather as a better vehicle. The following results were obtained by cutting from a very soft sheepskin leather strips, weighing about 1 gram, each. These strips were saturated with about their equal weight of oil and, together with an unimpregnated strip of skin, suspended on brass hooks. The changes in the weights of these strips were estimated from time to time and recorded in per cent. of the weight of the oil used:—

	Leather.	Olive Oil.	Sesame Oil.	Colza Oil.	Cotton-seed Oil.	Poppo-seed Oil.	Nut Oil.	Linseed Oil.	Cod Liver Oil.
Iodine number.....	—	82.1	119.2	162.4	169.2	137.9	129.2	155.8	171.6
After 1 day .....	0	0.2	0.1	0.1	— 0.1	0.3	— 0.2	0.1	— 0.6
" 2 days .....	1.0	1.0	1.2	1.1	0.8	2.0	2.0	1.5	1.1
" 3 " .....	1.3	1.2	0.9	1.3	1.4	3.2	1.4	2.0	8.1
" 4 " .....	0.9	0.9	0.5	1.0	1.2	4.3	7.1	3.8	16.0
" 5 " .....	1.4	1.4	1.1	1.8	3.1	7.1	9.7	12.3	10.9
" 6 " .....	— 0.6	— 0.4	— 0.5	0.5	2.2	7.3	8.4	11.8	8.0
" 7 " .....	1.3	1.1	1.0	2.5	5.0	9.7	9.6	13.2	16.4

" 9 " .....	0.5	0.5	0.7	2.8	5.7	7.3	7.3	11.3	8.5
" 10 " .....	1.8	1.7	2.0	4.6	7.4	8.0	8.3	11.8	10.4
" 14 " .....	— 0.5	— 0.4	1.1	2.3	2.5	3.3	4.0	7.0	6.8
" 3 weeks .....	1.1	0.7	4.7	3.2	1.6	2.7	4.2	8.2	6.3
" 4 " .....	3.3	3.5	6.6	6.3	5.2	6.7	8.4	12.6	11.8
" 6 " .....	— 2.5	— 2.5	— 0.5	— 0.2	— 1.4	— 0.3	— 1.3	4.5	4.3
Maximum.....	—	0.2	3.6	2.8	5.6	8.4	9.0	12.4	9.5
Livache's test .....	—	1.7	2.4	2.9	5.9	6.8	7.9	11.3	6.4
Calculated .....	—	5.2	7.0	6.5	6.9	8.6	9.4	11.1	10.0

These figures show that even the moisture of the strips of leather impregnated with oil varies in a similar degree as the moisture of the unimpregnated strip. While in Livache's test the maximum of the increase in weight is reached after two days' exposure, it takes very much longer in this new test, the time required probably varying with the temperature. With one or two exceptions, the above figures do not agree with those obtained by Livache's test. The theoretical oxygen absorption, calculated by multiplying the iodine numbers by the factor  $\frac{16}{253} (O = 16)$ , differs widely from the actual figures, from which it is evident that the oxidation of the oils does not consist in the addition of one atom of oxygen to each pair of doubly-linked carbon atoms. Moreover, oleic acid does not suffer any oxidation at all, and finally, after the maximum of the oxidation of an oil has been attained, further exposure results in a loss of weight caused, as Mulder showed, by the formation of volatile oxidation products, such as carbonic, formic, and acetic acid.—C. O. W.

PATENTS.

*Improvements in the Manufacture of Soap Tablets and Apparatus for that Purpose.* R. H. F. Finlay, Holywood, County Down. Eng. Pat. 4581, March 2, 1893.

The soap is run direct from the pan into a moulding machine, resembling that used for moulding candles, which may be mounted on transoms, so that it may be inverted if desired. The moulds are of circular or elliptical section. When the soap has set, it is exuded from the moulds by pistons worked by a rack and pinion, then cut up in the usual way, and pressed into tablets of any desired form. The soap may be variegated in colour by inserting a core into the mould before filling with soap, then withdrawing the core after the soap is set, and filling the cavity with soap of any other colour. Or tubes, closed at one end with a valve, containing melted colored soap, may be inserted into the moulds while the soap is still fluid, the valve opened, and the tube gradually withdrawn, when the different colored soaps commingle with each other.—J. J. K.

*Plates for Oil- and other Presses.* W. C. Leechman, Colombo, Ceylon. Eng. Pat. 7039, April 6, 1894.

See under I., page 377.

*Improvements in the treatment of Linseed Oil.* J. E. and C. S. Bedford, Leeds. Eng. Pat. 7742, April 17, 1893.

The claim is for a method of, and apparatus for, manufacturing a thickened or solid material from linseed oil (either raw or boiled) by exposing it in a finely disintegrated condition, at a high temperature, to the action of air. The oil is treated in a horizontal cylindrical steam-jacketed vessel (provided with a shaft, fitted with arms or beaters) which is only half filled, and heated by means of the steam jacket, assisted by agitation, sufficiently rapid to cause a spray. Air is forced into the space above the oil, when the finely-divided sprays of oil absorb oxygen. The temperature gradually rises till 120–160° C. is attained. Samples are taken from time to time, and when the desired consistency is obtained, the mass is run into coolers.—J. J. K.

*A New or Improved Composition of Soap.* Helen Hamilton, Cornacassa, Monaghan. Eng. Pat. 8621, April 29, 1893.

The following ingredients are blended together in approximate proportions, viz.:—

	Lb.
Best white ordinary soap .....	1
Whitening .....	1½
Washing soda .....	1
And about 1 pint of pure cold water.	

—J. J. K.

*An Improved Manufacture of Oils, Fats, Wax, and other analogous substances freed from odour or flavour.* C. D. Abel, London. From *Fabriques de Produits Chimiques de Thann et de Mulhouse*, at Thann, Alsace. Eng. Pat. 9105, May 6, 1893.

The main feature of this invention is to render oils, fats, &c. absolutely odourless and flavourless, and this is done by the exclusion of air from the closed vessels in which the substances are treated. They are heated in closed vessels and the air exhausted by means of an air-pump, or an inert gas, such as carbonic acid, nitrogen, or hydrogen, is introduced. After all the air has been removed, the temperature is raised to from 110° C. to 220° C., and saturated or superheated steam is then blown in until the condensed water is free from odour. In the case of fats, such as oleomargarin, which are easily saponified by steam, an inert gas is used instead of steam to remove the odorous products. The purification may be accelerated in some instances by first emulsifying the substance with 2 to 10 per cent. of sodium bisulphite of 40° B., and afterwards washing the fat with water, before treatment as above stated.—J. J. K.

*Improvements in Soap for removing Hair from the Skin.* J. Mellinger, Baltimore, Maryland, U.S.A. Eng. Pat. 18,658, October 5, 1893. United States Pat. dated March 16, 1893.

This invention relates to the intimate admixture with soap of sodium sulphide, which acts as the hair removing agent, starch as a binding agent, and glycerin, as an emollient. The proportions of the ingredients are—

Glycerin .....	1 lb.
Tallow .....	2 "
Coconut oil .....	2 "
" Oil of ricini .....	4 "
Soda lye (35 per cent.) .....	1 "
Starch .....	1 "
Sodium sulphide .....	2 "
Oil of citronella .....	1 "
Water .....	3 pints.

—J. J. K.

*An Improved construction of Hydraulic Oil Press.* Greenwood and Bailey, Limited, and H. Lambert, Leeds. Eng. Pat. 19,864, October 21, 1893.

The features of this invention are an adjustable measurer for feeding the meal, in order that the thickness of the cakes

may be regulated, and an arrangement to ensure an even pressure throughout the pile of cakes, whereby they are more equally consolidated, and a larger yield of oil is obtained.—J. J. K.

## XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

### (A).—PIGMENTS, PAINTS.

*Ultramarine.* Jordan. *Zeits. ang. Chem.* 1893, 684–690.

The possibility of artificially producing ultramarine dates from the time when Vauquelin discovered that the blue product found in soda furnaces had the same composition as ultramarine. Gmelin was the first to publish a method for preparing ultramarine, but the first factory was started by Guimet in Tonlouse in 1828. The author gives an historical account of the development of the industry, and then proceeds to describe the modern methods of preparation.

The requisite sodium sulphide may be obtained in three ways, viz., by—

- (a.) The sulphate process.
- (b.) The soda process.
- (c.) A combined sulphate and soda process.

The raw materials which are employed in the manufacture are:—

1. *Sulphate* or calcined Glauber's salt. This should not contain more than 3 per cent. of sodium chloride, and should be as finely divided and uniform in appearance as possible. Under certain circumstances the acid sodium sulphate is used in the manufacture of ultramarine green.

2. *Soda*.—The soda should be as free as possible from chlorine, but the strength may vary from 80–99 per cent. Ammonia-soda furnishes a product with a redder shade than Leblanc-soda. The Glauber's salt may be simply ground up with the soda in the combined process, but ultramarine of a purer blue tint is obtained if the solutions of the two are previously evaporated down together.

3. *Clay*.—The suitability of any given clay for the manufacture of ultramarine depends on what sort of product is desired. If purity of tint be no object, the percentage of iron may be considerable, but in all cases, clays with a high percentage of lime should be avoided. Clay is always used in a more or less finely divided state, just as in the manufacture of porcelain, and they may either be air-dried, or anhydrous, according to the kind of ultramarine it is intended to manufacture.

4. *Silica*.—The percentage of silica in clay is often too low, especially for the preparation of blue ultramarine with a reddish tint. In such cases finely ground quartz, sand, or kieselguhr must be added. Recently, the ignited residue obtained in the manufacture of aluminium sulphate, has been used for this purpose, but on adding it to the clay, allowance must be made for the alumina which is already contained in this substance.

5. *Sulphur*.—Sicilian, German, or English regenerated sulphur may be used, but it should be as pure as possible and free from arsenic.

Powdered coal, coal tar, or the resin obtained in the preparation of oil of turpentine may be used as the *reducing agent*. The first two are chiefly employed in the sulphate, the last in the soda process.

All the raw materials should be well ground, and it is also preferable to grind up the clay with the soda before adding the other substances. The materials may be mixed in many different proportions, and each corresponds to a slight variation in the colour of the ultramarine obtained.

Generally speaking, the stability of the ultramarine, with regard to alum solution, increases by increasing the proportion of silica. The depth of the colour increases by adding more sulphur and the reddish tint becomes more

apparent by increasing the proportion of silica. A large percentage of water in the clay gives a lighter ultramarine of a pure blue. In the combined sulphate and soda process, the character of the product may also be largely varied by altering the relative proportions of sulphate and soda. In the soda process a good blue may be obtained by adding to 100 parts of clay (with silica, if necessary) at least 70 parts of 95 per cent. soda, 80 parts of sulphur, and 14 parts of resin. For a pure sulphate ultramarine, 100 parts of clay, 105-130 Glauber's salt, and 25-30 parts of coal or tar may be employed. For the combined sulphate and soda process, equal parts of the above sulphate mixture and the following soda mixture are used. Clay 100, soda 100, sulphur 60, coal or tar 10-12 parts. A darker ultramarine is obtained by adding more of the last mixture.

The burning of the various mixtures is conducted in crucible furnaces, muffle furnaces, or in retorts, and the time required varies from 30 hours to 3-4 days. If insufficient oxygen is admitted to the crucibles, &c. the mass is green. Sulphurous acid, hydrochloric acid, &c. change the green colour to the usual blue at a high temperature. The blue mass is repeatedly ground (in the wet state), washed with water, and allowed to settle. Occasionally the finest particles of ultramarine settle with great difficulty, but the addition of a small quantity of salts of the alkalis or alkaline earths facilitates the process greatly. After drying by steam the ultramarine is passed through sieves of the required fineness.

Ultramarine violet may be prepared by a variety of processes. If a mixture of chlorine and steam is passed over ultramarine blue or green, heated to 160°-180° C., the violet colour is produced along with sodium chloride. Hydrochloric acid gas and air act in the same way when led over ultramarine heated to 150°-230°.

Ultramarine red is obtained when the vapours of nitric acid are led over ultramarine violet at 130°-150°, or the vapours of hydrochloric acid at 128°-132°.

Hydrogen converts ultramarine violet at 280°-290° into a pure bright blue substance containing hydrogen.

Ultramarine varies in composition so that it is not possible to represent it by a formula. The sodium may be replaced by silver, potassium, and lithium, and the sulphur by selenium and tellurium.

The following tables give the composition of some ultramarine compounds:—

## PATENTS.

*Improvements in Apparatus for the Manufacture of Metallic Pigments or Compounds, and in the Production of Lead Pigments or Compounds by Means of such Apparatus.* A. C. J. Charlier, Glasgow. Eng. Pat. 7117, April 6, 1893.

This patent refers to an improvement in the apparatus described by Hannay (Eng. Pat. 1282, 1889; this Journal 1889, 553) for the preparation of lead sulphate by the volatilisation method; and the improvement consists in the insertion of a damper between the producer furnace and the oxidising chamber, so as to prevent the pigment from being discoloured by the smoke given off from the freshly charged fuel, and in the employment of jets of steam in the furnace and chamber, which are stated also to prevent discolouration, "and the formation of slag in the oxidising chamber."—F. H. L.

*A New or Improved Paint.* W. Ward, South Shields, and J. O. Wallace, North Shields. Eng. Pat. 10,619, May 30, 1893.

This paint is claimed to be impervious to and not softened by petroleum oil, so that it may be used to protect any tanks or vessels used for storing this substance, being applied either to the fresh service, or on the top of any other kind of paint. It consists of 150 parts of wood naphtha, 50 of caoutchouc, 30 of shellac or lauri, 75 of coal-tar naphtha, 15 of "pine varnish," 20 of Stockholm tar pitch, 10 of boiled linseed oil, 30 of ground white lead, 20 of dry zinc white, and 150 of a suitable pigment, "pale celestial blue" being preferred. The mixture is made in a steam jacketed pan fitted with a stirrer, and the resulting paint is thinned with wood naphtha to a suitable consistency.

—F. H. L.

## (B.)—RESINS, VARNISHES.

### PATENTS.

*Improvements in the Composition and Treatment of Substances for Use as Glue, Putty, and Cement.* W. M. Walters, Liverpool. Eng. Pat. 3886, February 22, 1893.

One hundred parts of "resin" are melted with 2-20 parts of linseed oil, and 200-40 of a mixture of such substances as chalk, lime, plaster of Paris, fuller's earth, zinc oxide, &c.—F. H. L.

*An Improved Polishing Medium.* P. Theil and K. Schimnitz, Köpenick, Germany. Eng. Pat. 8666, April 29, 1893.

One hundred and twenty five grms. each of guaiacum and benzoin resins, 30 of shellac (preferably the "ruby" brand), 150 of linseed oil, and 30 of "benzine" dissolved in 3 litres of 94 per cent. spirits of wine, form a polish which may be employed by inexperienced persons and when applied is most durable, not being liable to exudation, when used for covering coats of oil-paint of long standing it will produce no cracks and will always prove durable and of satisfactory appearance."—F. H. L.

## (C.)—INDIA-RUBBER.

*Regenerated India rubber.* Rob. Henriques. Chem. Zeit. 17, 126°.

THE recovery of the india-rubber from golo-he- and similar articles forms an extensive branch of industry in the United States. The process by which this recovery is effected consists in the mechanical separation or destruction by means of dilute sulphuric acid, of the textile materials and the subsequent treatment of the finely ground product with steam under a pressure of six atmospheres. The steaming process seems to effect a devulcanisation by oxidation. This assumption is borne out by the fact of the regenerated india-rubber possessing, unlike vulcanised

rubber, to some extent the plastic properties of natural caoutchouc, and also by the results of an analysis, which showed the presence of a large quantity of sulphates and but little sulphur in combination with organic matter in the recovered product.

Various qualities of this regenerated or "reclaimed" rubber are met with in commerce. The price of these products, which at best represent but mediocre mixtures approaching closely in composition to the waste material from which they have been obtained is high (1s. to 1s. 6d. per kilo.), considering the quantity of real caoutchouc contained in them does not exceed 35 or 40 per cent. Their industrial value therefore appears doubtful. Three samples in the shape of black sheets, examined by the author, had a specific gravity of from 1.59 to 1.66, and contained lead oxide, calcium sulphate and carbonate varying in quantity from 12.23 to 14.02 per cent., 21.43 to 22.13 per cent., and 10.91 to 18.00 per cent. respectively, together with small quantities of ferric oxide, alumina, silica, and water. The sulphur in combination with caoutchouc amounted to from 0.71 per cent. to 2.03 per cent. Asphaltum and lamp-black, two invariable constituents of the goloshes mixture were also found to be present. Fatty oils and india-rubber substitutes could not be detected.—F. M.

*The Analysis of India-rubber Goods.* D. Holde. Chem. Zeit. 17, 1634-1635 and 1671-1671.

See under XXIII., page 425.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

*Estimation of Glue.* Papier Zeit. 19, 126.

See under XXIII., page 424.

*Examination of Glue for the Manufacture of Coloured Papers.* Th. Schlossmann. Papier Zeit. 18, 2484-2485.

See under XXIII., page 424.

*Analysis of Tanning Materials.* A Fölsing. Chem. Zeit. 17, 1770.

See under XXIII., page 426.

## PATENTS.

*Improvements in the Manufacture of Liquid Glue.* G. E. Wiese, Hamburg, Germany. Eng. Pat. 2079, January 31, 1894.

In 100 parts of water dissolve successively:—

	Parts.
Chloral hydrate.....	2
Ammonium sulphocyanide.....	5
Boric acid.....	3
Zinc chloride.....	0.5
Zinc sulphate.....	1
Glue.....	450

Stir frequently whilst mixing to prevent setting. "The chloral hydrate and ammonium sulphocyanide produce the necessary degree of fluidity, whilst the desired tenacity and elasticity are produced by the boric acid and the zinc salts."

—A. G. B.

*Process for the Production of Glue and Gelatin from Bones.* J. Grillo, Neumühl-Hamborn, Germany, and M. Schroeder, Düsseldorf, Germany. Eng. Pat. 2175, February 1, 1894.

WHEN air-dried or slightly-moistened bones are exposed to a current of sulphur dioxide at the ordinary temperature, they will absorb, with the exception of those of the very

hard, tubular kind, from 10 to 12 per cent. of their weight of the gas in the course of 12 hours. If the exposure be prolonged the absorption may increase to 15 or even 20 per cent. of the weight of the bones; but this excess will be lost when the bones are exposed to the air.

An absorption of 11 to 12 per cent. calculated on the weight of the bones amounts to 16 to 17 per cent. calculated on the inorganic constituents thereof, and corresponds with the equation—

The bones, treated in this way, are easily disintegrated by water at 100° C.; the sulphite and phosphate remain insoluble whilst the gelatin passes into solution.

In practice, the bones are placed in lead-lined wooden chests or in iron cylinders and treated systematically with gases carrying sulphur dioxide. Thus, if the installation consist of eight chests, four of these may always be in use for the absorption of the gas, three in a state of rest after the gas has been absorbed to the extent of 10 to 12 per cent., to allow of chemical combination of such gas as has been "fixed by condensation," and one in course of being charged or discharged.

"After shutting out apparatus 1, apparatus 5, with fresh bone material, is connected again. The sulphur dioxide gases then pass through the apparatus 2, 3, 4, 5 in succession, whilst 7, 8, 1 are in a state of rest. Apparatus 6, which has been standing longest, is then emptied, charged with fresh bones, and, in place of apparatus 2 to be shut out, connected in the set."

When compressed liquid sulphur dioxide is available it is better to treat the bones in separate iron cylinders under pressure; 10 to 12 cwt. of the liquid will be required for every 100 cwts. of bone.

The decomposed bones are transferred to lead-lined vats, covered with water, and heated by closed or open steam; after two or three hours the liquid is changed, to avoid loss of glue substance by prolonged heating. The second liquor is mixed with the first, the third is used for extracting fresh, decomposed bones. If the bones have not been subjected to extraction with solvents whilst raw, which is the better plan, the bone-fat will here be recovered by skimming. The glue liquor will be acid in reaction and will contain a small quantity of calcium sulphite and monocalcium phosphate in solution. These must be removed in order to obtain a transparent finished product; to this end the liquor is neutralised with milk of lime, whereby the salts are precipitated and may be filtered off. The evaporation of the glue solution is conducted as usual. From 16 to 24 per cent. of glue should be obtained.

The bone residue consists of a mixture of  $\text{CaHPO}_4$ ,  $\text{CaSO}_4$  and some inner hard pieces of unattacked bone (about 10 per cent. of the bone-). By grinding under gentle pressure and sifting, this unattacked bone may be separated and returned to the sulphur dioxide vats. The finer portion of the residue is treated in closed cylinders with sulphuric acid in order to render the phosphate completely soluble and to recover the sulphur dioxide.—A. G. B.

*An Improved Process for Continuously Treating Hides in Tanning Liquors, and Apparatus therefor.* H. W. Brüning, Neumünster, Prussia. Eng. Pat. 8026, April 20, 1893.

This process is characterised by finishing the tanning process in the same receptacle in which the hides were originally suspended, the liquor flowing continuously through the receptacle (and in each vessel from below upwards) in such a direction that the strongest liquor acts on the hides which are in the last treating period of the tanning process. The object is attained by means of channels arranged in the masonry walls of the receptacles in a manner set forth in the drawings which accompany the specification.—A. G. B.

## XV.—MANURES, Etc.

*The Action of Lime, of Salts, and some Acids in Rendering Clay Flocculent.* Rob. Saehse and Arthur Becker. Landw. Versuchsst. 1893, 43, 15.

PURE china clay suspended in water is, by the addition of a few drops of lime-water, immediately converted into the flocculent modification and precipitated. The lime does not enter into combination with the clay. Two samples of soil, treated in the same manner, behaved differently from each other, inasmuch as in one case the coagulation took place instantaneously and in the other very slowly. The action of the lime might furnish a means of altering the structural condition of a soil.

Acids have the same coagulating effect. Carbonic acid, which quickly causes the fine particles of china-clay to settle, might also to some extent be the cause of the improvement of a heavy soil by humoid substances. Hydrochloric, sulphuric, and nitric acids have a rapid action upon china-clay. Hydrochloric acid, in fact, seems to surpass all other substances in this respect. Salts are less effective generally, but sodium, potassium, and ammonium chlorides were found to flocculate china-clay and one of the two samples of soil quickly, whereas the other remained unaffected.

Silica in the form of infusorial earth and finely-ground quartz showed a behaviour similar to that of clay.—F. M.

*Comparative Experiments on the Fertilising Effect of various Phosphates.* O. Kelloer, Kozai, Mori, and Nagaoka. Landw. Versuchsst. 1893, 43, 1.

WHILE all phosphates (applied to non-irrigated soil) showed a distinct influence upon the three crops following the first one, the degree of this influence differed with the different phosphates. Thus superphosphate, precipitated calcium phosphate, phosphatic slag, and ground steamed bones showed a great similarity in their action. They were taken up chiefly by the first crop and their effect upon the succeeding crops became gradually less, the initial ratio of the respective manurial values remaining almost unaltered. This observation finds its explanation in the fact of the readily assimilable mono- and di-calcium phosphates suffering chemical changes in the soil, by which their solubility becomes reduced. The steamed bones and the precipitated calcium phosphate were almost identical in their behaviour, the organic substance of the former undergoing rapid decomposition in the soil, through which the effect of the phosphoric acid becomes accelerated. Raw bones, on the other hand, had less influence upon the first crop, but proved far more effective and lasting as regards the succeeding crops. In this case, again, bones not freed from fat were found superior to extracted bones. The fatty acids set free by the dissociation of the glycerides seem, therefore, to play a definite part in rendering the phosphate soluble.—F. M.

*Potassium Phosphate as Manure.* Theodor Meyer. Chem. Zeit. 17, 1267.

THE attempts hitherto made to produce potassium phosphate cheap enough to render its use as a manure possible have met with little success. A process has been worked out by the author, which is founded upon the reaction expressed by the following equation:—

In actual working this reaction does not proceed smoothly, for by the direct action of the phosphoric acid upon the calcium carbonate calcium phosphate is produced, which means a loss. The necessary operations of filtering, washing, and evaporating would also increase the cost of production. By replacing the calcium carbonate, necessary for the carrying out of the process, by so-called *craye grise* or

chalk-phosphate, not only the manufacture of cheap potassium phosphate becomes possible but also the solution of the problem of advantageously utilising the extensive deposits of this mineral, occurring near Mons, is arrived at in a satisfactory manner. It is carried out as follows:—A measured volume of phosphoric acid of known strength (about 10 per cent) is mixed with the required quantity of potassium sulphate and then the calculated amount of the finely-ground chalk-phosphate (*craye grise*) is gradually introduced. After the lapse of an hour or so the phosphate solution is filtered off and evaporated to a pasty consistency. Desiccation is completed in chambers heated to 70–80 °C. The residue left in the filter-press is without previous washing treated with sulphuric acid in order to decompose the calcium phosphate contained in it. The washings from the calcium sulphate, which forms the only refuse, are utilised in diluting the sulphuric acid for the next operation. The finished product contains from 38 to 40 per cent. of phosphoric acid ( $\text{P}_2\text{O}_5$ ) and 31 to 33 per cent. of potassium oxide, besides a few per cent. of sulphuric acid. Its value as a manure is obvious.—F. M.

*Valuation of Ground Phosphatic Slags.* E. Wrampelmeier. Landw. Versuchsst. 1893, 43, 183.

See under XXIII., page 422.

*Decomposition of Liquids by contact with Powdered Silica.* G. Gore. Phil. Soc. of Birmingham, 1893.

See under Analyt. and Scient. Notes, page 428.

## PATENTS.

*Improvements in the Manufacture of Soda and Monocalcic Phosphate.* F. Hurter, Widnes, Lancaster, and J. Omholt, Christiania, Norway. Eng. Pat. 7107, April 6, 1893.

See under VII., page 391.

*Improvements in the Manufacture or Production of Monocalcic Phosphate and Ammonia.* F. Hurter, Widnes, Lancaster, and J. Omholt, Christiania, Norway. Eng. Pat. 7108, April 6, 1893.

Dry ammonium sulphate is mixed with ground tricalcium phosphate, preferably in the form of a high grade mineral phosphate, in proportion of about 0.85 parts ammonium sulphate to each 1 per cent. of phosphate in the mineral, though it is preferred to use the phosphate in excess. The mixture is heated in a current of superheated steam in a horizontal east-iron cylinder, exposed to direct fire to a temperature of from 550° to 650° F., and the ammonia evolved is led to a condensing apparatus, in which the steam condenses with some ammonium sulphate. The ammonia gas may be utilised for any purpose, such as for the manufacture of soda by the ammonia process. The contents of the cylinder are cooled to about 220° F. by passing in low pressure steam, and are then withdrawn to be ground up as a manure. It is preferred to add 10 to 15 per cent. of sulphuric acid, to react upon any unaltered tricalcium phosphate. If the mass is damp, it may be dried at a temperature not exceeding 212° F.—E. S.

*Improved Manure or Fertiliser.* W. Brothers, Rawtenstall. Eng. Pat. 7537, April 14, 1893.

THE inventor claims the use of solid carbonates of ammonia in a crystalline or powdered form, being superior to either sulphate of ammonia or nitrate of soda, as it is less soluble, more easily decomposed as required by the plant, and the whole weight of the carbonate is utilised. For horticultural purposes it may be used in solution.—J. J. K.

## XVI.—SUGAR, STARCH, GUM, Etc.

*The Decomposition of Invert Sugar by Alkalis and the Practical Application thereof.* Priusen-Geerligs. Chem. Zeit. Rep. 1893, 299—300.

DURING the manufacture of raw sugar from the sugar cane, the presence, or formation, of invert sugar and its decomposition products is an objectionable factor, leading, as it always does, to acidity and fermentation. In order to avoid these difficulties, it is necessary to destroy the invert sugar and allied bodies present in the juice at the very outset. For this purpose the freshly-expressed juice is treated with a slight excess of lime, the excess removed by carbonic, phosphoric, or sulphurous acid, the liquid again treated at a moderate temperature with a small quantity of lime, and, finally, a little barium chloride added. Experiments on a large scale made on a sugar plantation in Java showed that by this means the amount of invert sugar in the juice could be reduced to a minimum, and its subsequent formation (from cane sugar) almost entirely arrested, providing reasonable precautions were observed as regards cleanliness of plant and risk of infection.—H. T. P.

*Note on the Influence of the Percentage of Fat in Sugar-Beet Seed, and the Size of the Latter, on the Richness of the Resulting Beets in Sugar.* P. Doerstling. D. Zucker J. 1893, 1566.

THE author cannot confirm Laskowsky's theory, according to which (1) the richness of the beet in sugar is dependent on a corresponding richness of the seed in fat, and (2) the larger species of seed yield (larger) beets poorer in sugar. Twenty-two varieties of seed and the tubers grown therefrom were examined. From the results it appears that there is no connection whatever between the weight of the beets and the percentage of sugar contained in them, on the one hand, and the size of the seed on the other; whilst the following figures show that variations in the percentage of fat in the seed do not appreciably influence the quality of the resulting beets.

*Seed Rich in Fat* (average of eight samples).—Fat, 16·6 per cent.; sugar in the beet, 14 per cent.; weight of beet, 240 grms.

*Seed Poor in Fat* (average of five samples).—Fat, 12·8 per cent.; sugar in the beet, 14 per cent.; weight of beet, 215 grms.—H. T. P.

*Compounds of Sugars with Iron.* F. Evers. Ber. 27, 474—475.

See under XX., page 415.

## PATENTS.

*Improvements in Apparatus applicable for Evaporating Liquids or Saccharine Solutions.* J. A. Morrell and J. Fromherz, both of New Orleans, U.S.A. Eng. Pat. 3170, February 13, 1893.

See under I., page 377.

*Improvements in or Appertaining to the Utilisation of a Waste or Nearly Waste Product, and the Manufacture of a Useful Gum or Gummy Compound therefrom.* J. Hanson, P. C. D. Castle, and J. H. Morrison, Liverpool. Eng. Pat. 8793, May 2, 1893.

FROM the beans of the locust or carob tree, the inventors extract a gum which they call "tragasol," which may be used to replace tragacanth, size, &c., in weaving, dyeing, and printing cloth. The kernels are split in a bean-splitting machine, the germs and pods carefully removed by aspiration and riddling, and the residue extracted with boiling water until a homogeneous mass is obtained, which is then

put through a centrifugal machine. The liquid may, if necessary, be evaporated to a thick paste, and it will keep for 10 days without the addition of any antiseptic. The specific gravity is about the same as that of water. Care must be taken during the manufacture to prevent the gum coming in contact with either iron, steel, brass, or copper, as it would be discoloured by them.—F. H. L.

## XVII.—BREWING, WINES, SPIRITS, Etc.

*Raw-Grain Conversion in the Brewery.* A. Gordon Sakauon. Trans. Inst. of Brewing, 7 [2], 1893, 31—47.

PRIOR to the year 1880—when duty was levied on the malt, instead of, as at present, on the wort—the use of raw (unmalted) grain was entirely prohibited. Since the restriction has been removed, however, raw grain has come into considerable prominence, chiefly owing to its cheapness as compared with malt. For instance, the average cost of 1 lb. of extract from good barley, prepared rice, and maize, is 5d., 4d., and 3½d. respectively. Apart from cost, another advantage consists in the almost absolute freedom of these malt adjuncts from mould, &c. Malt, as a necessary consequence of the mode of its production, always contains more or less mould, which, if present in excess, exerts a pernicious influence on the resulting beer. In this connection the author has made experiments to determine the minimum percentage of moisture which must be present in rice or maize in order that mould can develop, and finds it to be about 20 per cent. If the moisture be much below this amount no mould-growths appear, even after prolonged incubation of the grain at 100° F. Since the water in rice and maize does not usually exceed 12—14 per cent., it follows that the brewer should rigidly reject all samples containing the least trace of mould. There is one disadvantage attending the use of raw grain, which applies more particularly to maize, and arises from the comparatively large amount of oil existing in that cereal. The oil in maize averages 3—4 per cent., and sometimes attains 5 per cent.; and, like other similar oils, it is most readily decomposed, especially when heated to a temperature exceeding 200° F., into products (free fatty acids) of a most offensive character. This oil, if retained in maize to any extent, would absolutely prevent the latter from being used in large proportions by the brewer. There is little doubt that the "greyness," which at the outset characterised maize beers, was due to the presence of finely-divided oil. The oil of rice, although smaller in amount, is also objectionable. Smetham has described these oils, and the author quotes some of his figures (this Journal, 1893, 848). Fortunately the oil, being chiefly contained in the germ and husk, may be readily removed by mechanical means and reduced to 0·5 per cent. (in the prepared grain). The author suggests that this figure should be adopted by brewers as the maximum permissible amount.

As regards flavour, it is interesting to note that although the starches of maize and rice do not apparently differ chemically from barley-starch, yet the beers produced from them have a distinct character of their own. Rice imparts a dry flavour and the beers clarify readily, whilst maize yields a full, round, smooth flavour, very suitable for "running" beers.

The form of prepared grain mostly used in this country is that known as "flakes." In its manufacture the seed is crushed between suitable rollers and carefully graded until all the broken starchy particles attain as nearly as possible the same size. At the same time, by an exhaust suitably arranged, the liberated germs, husk, and meal, which are much lighter than the starch-particles, are separated. The product thus obtained, known as "grits," is gelatinised by means of steam. It is of importance that this operation be not conducted too quickly, otherwise there is a risk of vitrifying the outside of the grits, and of thus preventing or retarding the satisfactory rupture of the starch cells.

After gelatinisation the grits are flattened out into the familiar form of flakes by being passed between steel rollers, and finally dried on heated floors. It has been suggested that high drying at this stage would be beneficial because tending to the production of dextrin; but this advantage is counterbalanced by the fact that high drying leads to vitrification and consequent loss of extract.

As regards the percentage of raw grain that it is possible to use, general experience shows that 20—25 per cent. is about the limit, and even then great care must be taken to mix the material thoroughly with the malt grist. If appreciably more be employed the excess is simply not dissolved, and leads to bad drainage and other evils. Many attempts have been made to devise methods permitting of the admixture of a largely increased percentage of raw grain with the malt, but so far with little success, at least in this country. The most perfect process and apparatus at present known is that designed by Billings (this Journal, 1892, 628 and 833), and, according to the author, by means of this process 50 per cent. of raw grain (grits) may be incorporated with the malt without the slightest injury attaching to the resulting beer.

In the discussion which followed the reading of the paper, the main points raised related to the Billings apparatus. Going into the question of flavour, the author stated (in agreement with another speaker) that the beers produced

by its means compare favourably as regards flavour with ordinary beers. He further laid stress on the fact that in Billings' process the maize is not boiled as in the older methods, and that consequently no fear need be entertained on the score of the decomposition of the maize oil into objectionable flavouring bodies. As regards extract, the author admitted that the results at the outset were rather poor, owing to gross errors in manipulation, but that at present excellent results were obtained. Concerning the influence of raw grain processes on yeast, the author stated that from worts produced in Billings' apparatus perfectly healthy and vigorous fermentations were obtained, and that the appearance of the yeast under the microscope was all that could be desired.—H. T. P.

*Note on the Composition of Hops; and the Influence of Hops on Wort.* L. Aubry. *Zeits. f. d. ges. Brauw.* 17, 1894 [1], 1—2; [2], 9—10; [3], 17—18.

A RECORD of investigations carried out at the experimental brewing station of Munich. Analyses of wort before and after boiling with hops are given, from which it appears that the composition of the wort, especially as regards the total and albuminoid nitrogen, is practically unaltered by the treatment with hops. The analyses of various samples of hops are given in the following table:—

Source.	Moisture.	Percentages on Dry Substance.							
		Alcoholic Extract.	Benzene Extract.	Water Extract of Sample previously extracted by Alcohol.	Total Nitrogen.	Water-soluble Nitrogen.	Tannin.	Resin.	Water Extract.
1. Posen.....	8.08.	45.50	30.10	14.20	2.11	0.69	5.32	19.46	25.88

The above hops were also examined after the resins had been extracted by petroleum ether. The results show that only minute traces of tannin and nitrogenous bodies are dissolved during such treatment.

*Ripe and Unripe Hops.*—It is well known that practical brewers ascribe various objectionable effects to the use of unripe hops. Investigation proved that, chemically, there is no difference whatever, either before or after fermentation, between worts prepared under identical conditions with ripe and unripe hops respectively. The matter resolves itself simply into a question of aroma and flavour. Unripe hops yield very little aroma, and impart a harsh flavour to beer.

*Russian Hops* are daily coming into greater prominence, and compete favourably as regards quality with the home-grown article. A sample (1891 crop) yielded the following figures on analysis:—Moisture, 9.38 per cent.; benzene-extract, 31.06 per cent.; alcoholic extract, 49.66; water-extract, 28.80; tannin, 5.33 per cent.; total nitrogen, 2.46 per cent.

The remainder of the paper is devoted to the description of a number of fermentation experiments, in which worts hopped with different brauds of hops were employed. The various results obtained are tabulated. The general conclusion to be drawn from them is, that, other conditions

being equal, the quality of the hops used, exerts no influence on the attenuation and chemical composition of the resulting beer.—H. T. P.

*The Carbohydrates of Yeast.* F. Salkowski. *Ber.* 27, 497—502.

THE liquid obtained by boiling yeast with water, although possessing no reducing action, is shown by the author to contain at least two carbohydrates. One of these—a gum—is precipitated by Fehling's solution in the form of a copper compound; the other remaining in solution yields with iodine the coloration peculiar to glycogen, &c. The former appears to be derived from the contents of the yeast-cells, the latter from the cellulosic tissue. The author has for the present more particularly studied the gum, the method adopted for its isolation being as follows:—Pressed yeast (1 part) is boiled for half an hour with 3 per cent. potash solution (10 parts), allowed to cool and settle, and the clear portion decanted off and heated on the water-bath with Fehling's solution (1½ parts). The bluish tenacious mass which separates in a lump is quickly removed from the liquid, slightly washed with water, ground up with water, and redissolved by the cautious addition of hydrochloric acid. From the resulting turbid solution the gum

is precipitated by adding 3-4 volumes of 90 per cent. alcohol. The precipitate may be purified by re-solution in water and reprecipitation by a large excess of absolute alcohol, and should be finally dehydrated by trituration with absolute alcohol, followed by ether. Thus obtained, the gum forms a white, friable, non-hygroscopic powder, having, when dried at  $110^{\circ}\text{C}$ ., the composition  $\text{C}_{12}\text{H}_{16}\text{O}_{11}$ . It is very soluble in water to a bright pale yellow solution, which when strong is very viscous, and leaves on evaporation a residue greatly resembling gum arabic. The gum is dextro-rotatory— $[\alpha]_D = 90^{\circ}10$  in about 2 per cent. solution.

A weak solution of the gum yields no reaction with neutral or basic lead acetate, ferric chloride, or tannin. Barium hydrate produces at first a turbidity, then a stringy precipitate. Ferric chloride, or basic lead acetate, in conjunction with ammonia, yield a jelly-like mass or precipitation. The reaction with Fehling's solution is so delicate that one part of gum in 5,000 of solution may be precipitated by its means.

On heating with acids the gum is converted into a slightly dextro-rotatory, fermentable, reducing sugar. The yield of gum from pressed yeast appears to be about 2 per cent., equal to 6.9 per cent. calculated on the dry matter.

—H. T. P.

### PATENT.

*Improvements in the Preparation of Malt and in Apparatus therefor.* R. Genge, Hamburg. Eng. Pat. 24,548, December 20, 1893.

THESE improvements relate to the pneumatic system of malting, and are claimed to effect the supply to the grain of cooled air of a constant temperature, and also to maintain a constant degree of humidity within the drum, while allowing for the removal of the carbonic anhydride formed during germination. The air supplied to the drum passes through a tube, around which a system of tubes, containing a cooling medium, is arranged. These tubes also circulate within the drum, and are there claimed to effect the maintenance of a constant degree of humidity by condensing moisture from the air and re-communicating it to the grain. The removal of the gaseous products of germination is attained by perforating the circular wall of the drum and placing round it a series of flaps, which, as the drum rotates, are so arranged as to close the holes in the then upper parts of the drum walls, and to leave open those in the lower parts.

—J. G. W.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY AND WATER PURIFICATION, DISINFECTANTS.

### (A).—CHEMISTRY OF FOODS.

*The Changes Produced in Bread by Mould.* Hebebrand. Landwirthschaftl. Versuchsst. 42, 421-427.

THE changes which bread undergoes during the growth and development of the mould fungus involve principally the consumption of the carbohydrates. Since no evolution of nitrogen in the form of ammonia seemed to occur, it would appear that a proportionate increase of albuminoids must have taken place in the mouldy bread. Nevertheless, it must be observed that a considerable portion of the nitrogen will then no longer exist as albumin, but in the form of decomposition products thereof.—W. S.

*Margarin rendered Conspicuous by Admixture of Phenolphthalein.* F. Hart. Chem. Zeit. 17, 1908-1909.

SOXHLET has recommended that all margarin should be compulsorily impregnated by the manufacturer with phenol-

phthalein; whilst, on the other hand, it has been urged that this admixture would render the substance uneatable in a week. The author finds that this is not the case, addition of from 0.002 to 0.006 part of phenolphthalein having no injurious effect of any kind on 50 parts of margarin, even after keeping six weeks; the samples were perfectly eatable, and gave a red coloration on shaking with soda in a test tube. Moreover, quantities of phenolphthalein varying from a centigram. to 0.2 gram. taken at breakfast produced no evil result of any kind, although somewhat larger doses (0.3 to 0.5 gram.) produced slight diarrhoea. The quantity of phenolphthalein recommended by Soxhlet to be added to margarin (to facilitate detection of adulteration of butter) would only amount to 0.3 gram. in 13.6 lb. (German) of material.—C. R. A. W.

*The Poisonous Action of Martins Yellow, and its Detection.* D. Vilali. Boll. Chim. farmac. 1893, 32, 738.

See under XXIII., page 423.

*Note on some Modifications of the Reichert Meissl Method of Detecting Margarine in Butter, and a New Method for the Determination of the Reichert-Meissl Number.* C. Bunte. Chem. Zeit. 18, 204-206.

See under XXIII., page 427.

*New Method of Estimating Pentosans in Vegetable Substances.* E. Hotter. Chem. Zeit. 17, 1743.

See under XXIII., page 424.

### PATENT.

*A New or Improved Treatment or Preparation of Cream and its Employment in the Manufacture of Butter or for other Purposes.* C. A. Mountfort and J. Prior, Wellington, New Zealand. Eng. Pat. 5527, March 14, 1893.

WHEN butter is made for transport in a cold or frozen state to long distances, salt has to be used, and at the end of the time required for transport it is in a mealey or crumbling condition, and not likely to find a ready sale. The inventors find it preferable to transport cold or frozen cream instead of frozen butter. It is found that the butter made from the frozen cream after its transport is indistinguishable from butter made with the same quality of cream in the fresh state.—V. C.

### (B).—SANITARY CHEMISTRY AND WATER PURIFICATION.

*Treatment of Municipal Refuse in Podewil's Faecal Extract Factory at Augsburg.* Chem. Zeit. 18, 68-69, and 102.

THE possibility of dealing with faecal matters so as to make a profit out of the resulting manure, depends largely on the system of collection; small vessels (tubs) usually receive only a portion of the urine, and little or no household slops, whilst larger receivers (cesspools) often contain the latter to a large extent; hence, whilst the estimated value of the faecal matters from towns where the tub system is adopted is as high as six or eight marks per cubic metre (1,000 kilos.), that in cesspool towns falls to only four or six marks. As regards quantity of excrement per head, the usually received statistics on this point are widely incorrect; the results of the measurements at Augsburg indicate that the individuals from whose excrements the statistics were deduced must have eaten a good deal more than the average population consumes per head in Germany and Austria—a point of much importance in all calculations respecting the treatment of excrementitious matter.

The system adopted at Augsburg consists in mixing the faecal matter with acid and drying for several hours at 120° C. in closed rotating vessels, so that the resulting solid matter issues as a dry powder, whilst the evolved vapours are condensed by a 15-fold supply of river-water to a fluid which has no evil effect on fish, and is not perceptible a few yards lower down stream than the point of inflow. No nuisance of any kind exists; the factory is only two kilometres (1½ miles) from the centre of the town, and is in the vicinity of dwelling-houses, large shops, a school, and other residences.

The same system, with modifications, is also in use for disposing of carcases and abattoir refuse, including blood and similar materials; the closed vessels are made stronger, so that by the aid of high-pressure steam the temperature can be raised to 160° C.; fatty matters are thus melted out and utilised as such, whilst the residue is dried and pulverised whilst still in the same chamber, thus involving a great improvement on other forms of apparatus where treatment with high-pressure steam, drying, and grinding, are three separately conducted operations. It is not practicable to prepare any useful glue from such materials, excepting when clean bones only are used; in all other cases a gelatinous meat broth is obtained, only capable of use in manure making. Podewil's apparatus dries up all such extracts along with the more solid portions of the carcases, producing a readily marketable powdered manure; whilst fat and condensed vapours are the only other products; since all the operations are conducted throughout without exposure to air, any unpleasant smell is practically avoided, and no removal or handling of products at intermediate stages is requisite. In addition to 12 years' experience at Augsburg, the system has also been adopted on the large scale at Hamburg; and smaller arrangements are also in use in Munich and Barmen.—C. R. A. W.

*The Determination of the Reducing Action of Organic Substances contained in Water upon Permanganate of Potassium.* A. Zega. Chem. Zeit. 18, 2.

See under XXIII., page 427.

*Decomposition of Liquids by contact with Powdered Silica.* G. Gore. Phil. Soc. of Birmingham, 1893.

See under Analyt. and Scient. Notes, page 428.

## PATENTS.

*Improvements in or connected with the Purification of Sewage and Analogous Foul or Impure Liquids.* J. J. Meldrum and T. F. Meldrum, both of Manchester. Eng. Pat. 6423, March 27, 1893.

THE inventors claim as chief improvement the purification of sewage by forcing it into and through the air in the form of a fine spray or rain. Before aerating, the sewage may also undergo a preliminary purification by means of iron salts or similarly acting materials; or it may be charged with sulphureous acid.

The projection of the liquid in the form of spray or rain may be effected by applying centrifugal force. The sewage is forced, under suitable pressure, to nozzles or discharge pipes, which are provided with internal twisted blades or screws having one or more deep threads, or are rifled or equivalently formed, by which the liquid is given a circular or gyratory movement as well as a forward motion, causing it, after leaving the nozzle or discharge pipe, to fall apart or be distributed in the form of fine drops or spray.

The inventors describe four other means of attaining the desired spray. Very bad sewages, particularly if not previously chemically treated, must be subjected to aeration more than once.—L. de K.

*A New and Improved Method of Connecting Joints in Sanitary Earthenware and other Articles.* A. and F. G. Johnson, Hanley, Staffordshire. Eng. Pat. 9765, May 16, 1893.

See under I., page 378.

*Improvements in Apparatus for Sterilising Water.* N. Yagin, St. Petersburg, Russia. Eng. Pat. 9808, May 16, 1893.

THE inventor claims as improvement the continuous production of boiled cooled water, by means of a boiler in combination with a cooler, the boiler being composed of an upright closed vessel having passed through it a tube, the lower end of which is connected with a lamp, so that the heat of the latter is conveyed through the flue to the surrounding water. The cooler is constructed of a long upright chamber, containing tubes through which the boiler water is made to flow in one direction, while the water supply to the boiler is made to pass through the chamber surrounding the tubes in the contrary direction. The cooler may be readily taken to pieces. The apparatus is also provided with a regulator in conjunction with a steam coil, the pressure of steam in which controls the action of the regulator upon the discharge of water from the boiler.

As the water cools down under continued pressure, most of the air which has been expelled by the boiling will become reabsorbed, and the water, on storage in vessels, will not assume an unpleasant flavour.—L. de K.

## (C.)—DISINFECTANTS.

### PATENTS.

*An Improved Disinfecting Oven.* O. Baumbach, Copenhagen, Denmark. Eng. Pat. 813, January 13, 1893.

THE claim of the inventor is that the apparatus consists of two steam-tight chambers, one inside the other. The articles to be disinfected are placed on a perforated shelf in the inner chamber and heated by compressed steam circulating in the outer chamber. Condensation water free from dirt may, if desired, be admitted through perforations in the bottom of the inner chamber, and its supply and pressure regulated as required.

The faults of previous inventions are (1) that the articles are heated by direct contact with the steam, and hence are soaked with condensation water, and (2) the rust and oil of the apparatus itself soils the article under process.—L. de K.

*Improvements in or connected with Disinfectants.* P. Molyneux, Bow, and G. R. Potts, South Shields. Eng. Pat. 6953, April 1, 1893.

BLACK sea oil, creosote, caustic soda, resin, and "albo-carbon" (naphthalene) are mixed in various proportions, the resulting solution constituting a liquid disinfectant. The sediment from this solution is mixed with slaked lime, and powdered, forming a solid disinfectant.—J. G. W.

*A New Antiseptic Material.* S. Pitt, Sutton, Sarrey. Eng. Pat. 7038, April 5, 1893.

THIS consists of a 40 per cent. solution of formaldehyde to which the name "formalin" is given. It is claimed to possess a more powerful antiseptic action than corrosive sublimate or carbolic acid, and to have but a small poisonous effect on the human organism. It is stated to have a considerable antiseptic power, even when diluted in the proportion of one part to several hundreds of water. It is preferably prepared by passing air through methyl alcohol, and then over gently heated copper gauze, the surface of which is more or less oxidised. The mixture of air and gaseous formaldehyde is then passed through water, which will dissolve about 40 per cent. of the formaldehyde.

—J. G. W.

*Improvements in the Preparation of Antiseptics.* S. Pitt, Sutton, Surrey. Eng. Pat. 8429, April 26, 1893.

THE commonly used antiseptics, when applied in surgery in the form of dilute aqueous solutions, are stated by the inventor to have the disadvantage of coagulating albuminous solutions, and so being rendered inert as regards disinfecting purposes. To avoid this it is proposed to dissolve these antiseptics—viz., the various phenyl bodies employed and inorganic and organic silver salts—in a solution of either of the following organic bases: ethylenediamine and its alkyl derivatives; the bases obtainable from mono-chlorhydrin, dichlorhydrin, epichlorhydrin and ammonia, and also piperazine. These organic bases are claimed to be neither caustic nor toxic, and to produce a solution of the antiseptic which will not coagulate albumen.—J. G. W.

*Improvements in or connected with the Rolls of Machinery for Mixing and Calendering India-Rubber or other Materials.* A. G. Brookes, London. From J. E. Davis, Lynn, Mass., U.S.A. Eng. Pat. 21,095, November 7, 1893.

See under 1., page 378.

*Apparatus for the Production of Ozone from Phosphorus for Disinfecting Purposes.* S. F. Kattenhoy, Berlin. Eng. Pat. 24,709, December 22, 1893.

WITHIN a glass vessel, provided with a cover pierced with several holes, are suspended two or three small glasses by means of an adjustable rod. These glasses are provided with inlet holes at the bottom, and are arranged to carry pieces of phosphorus and to keep them just above a solution of potassium permanganate in 10 per cent. sulphuric acid. They are each covered by a small cap, which allows of the entry of air through one small opening and of the outlet of the phosphoric acid (?) produced, by a second and somewhat higher opening, and, at the same time, prevents ignition of the phosphorus taking place. The ozone produced during the oxidation of the phosphorus escapes into the air of the room to be disinfected through the perforations in the cover.—J. G. W.

## XIX.—PAPER, PASTEBOARD, Etc.

*Parchment Paper.* By a Practical Man. Papier Zeit. 18, 2717, 2750, and 3117.

IN the manufacture of parchment paper there must be absolute purity of raw material, entire freedom from lime, soda, alumina, chlorine, &c., and the web must be as spongy as blotting paper, without any sizing whatever. Its composition varies with the different strengths required, the thicker the parchment paper the softer, looser, and more permeable the raw material must be, whereas for medium and thinner qualities, it should be somewhat harder and more resistant. For thick paper weighing from 75 to 150 grms. per square metre, it is advisable to use cotton half-stuff, to allow, after bleaching, to remain for some time in the draining-boxes, to submit it to the same treatment as blotting paper, and, if necessary, to give it another bleach. Careful treatment of the finished pulp in the Hollander is also of importance. The thicker the web, the finer the pulp must be, whilst for thinner sorts the fibre should not be too short. In the machine the thicker varieties should be handled, so to speak, without pressure, whereas the thinner varieties must be subjected to slight pressure in order to enable them to withstand the parchementing operation. For certain qualities of thicker paper, in particular for osmosis parchment, as used in the sugar factories, an addition of 30–50 per cent. of linen pulp is necessary.

In the thinner sorts, weighing 30–45 grms. per square metre, soda and sulphite wood-pulp have been employed for

many years with good results. Mechanical wood-pulp is totally unfit, but a certain amount of bleached straw-pulp is not objectionable.

In the process of parchementing, two receptacles are required—one, on a higher level, for reducing the concentrated sulphuric acid to 56° B.; the other, on a lower level, for the reception of the cooled acid ready for work. The latter must be thoroughly mixed before using, and the vessel containing it closed with a lid. Temperature is of great importance and should not exceed 18° C., nor should the strength of the acid fall below 56° B. Care must also be taken to use a perfectly dry web in one piece, to reduce the proportion of acid to a minimum, and to avoid folds during the running.

Fig. 1 is a section of the parchementing apparatus. From the roller *a* the web passes into the lead-lined trough *d*

Fig. 1.

containing the acid, and next into the water trough *f*. It is then partly washed on both sides by the jets issuing from the perforated tubes in *g*, and finally, after passing round the roller *c* is wound up on *b*. Thorough washing being indispensable, each machine is provided with two or more systems of jets similar to the one shown in the drawing. After

Fig. 2.

washing, the parchment, unless it be required hard, is passed through a solution of glycerin and soda crystals and again rolled up, when it is ready for drying. The softer the paper is required, the more glycerin must be used. The dyeing of the paper, when requisite, must precede the glycerin treatment.

Owing to the fact that it contracts more than ordinary paper, parchment paper is more difficult to dry. Fig. 2 shows a simple form of machine. From the roller *k* the web runs over roller *l* on to the drying cylinder *m*, and winds itself up again on *n*, which is pressed against the drying cylinder by the lever weighted at *q*. In this, as in the previous operation, great skill and experience are required on the part of the workman directing the machinery.—E. G. P. T.

*Examination of Glue for the Manufacture of Coloured Papers.* T. Schlossmann. Papier Zeit. 18, 2484–2485.

See under XXIII., page 424.

*The Dyeing of Paper in Pulp.* H. Falke. *Farb. Zeit.* **5**, 97—100 and 113—116.

See under VI., page 389.

#### PATENTS.

*A Process for Colouring Paper and Cardboard.* F. R. Wells, Southgate, Middlesex. Eng. Pat. 8167, April 22, 1893.

See under VI., page 391.

*Improvements in the Manufacture of Cellulose.* C. Kellner, Vienna, Austria. Eng. Pat. 21,275, December 16, 1893.

WHEN wood is boiled under high pressure, the resulting cellulose is capable of being well bleached, but is deficient in strength; on the other hand, when boiled under low pressure, the resulting cellulose has considerable tenacity, but cannot easily be bleached. To obviate these disadvantages, the wood is boiled under high pressure in the cellulose apparatus, and the resulting cellulose, which is therefore capable of being easily bleached, is diluted with a considerable amount of water and treated in apparatus, such as a rag engine, opening machine, or separator, in order to detach the fibres from each other, and cause them to become intermingled. Hitherto they have been conducted direct to the paper-making machine, but according to the present invention the fibrous mass is first thickened into a pulp by removing surplus water, and afterwards subjected to the action of a beating apparatus, such as that of a mill-course or of a ball-mill. A mass is thus produced which, when thinned with water, is suitable for treatment in the paper-making machine, and which, besides being tenacious, is also capable of being easily bleached.

—E. G. P. T.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

*The Manufacture of Oxygen from Calcium Plumbate.* G. Kassner. *Chem. Zeit.* **17**, 1242.

NOR only the ease with which this compound dissociates on application of heat and takes up oxygen again from the air, constitutes, as accepted by Le Chatelier, its valuable properties for the preparation of that gas and its partial superiority over the barium peroxide used in Brin's process, but the further possibility of obtaining as a by-product pure carbonic acid, and effecting a saving in fuel and reduction in wear and tear of apparatus.

The method of using the plumbate consists in exposing it, in the shape of porous lumps, slightly damped with steam, to the action of washed combustion-gases at a temperature below 100° C. Carbonic acid is readily absorbed, and a mixture of lead peroxide and calcium carbonate results. The oxygen is expelled from the saturated product in a retort maintained at a red heat, preferably with the assistance of superheated steam. With the gradual rise of the temperature and the continued action of the steam, carbon dioxide is also set free, and is collected separately. The mixture of oxygen and carbonic acid produced at the intermediate stage of the process, likewise furnishes pure oxygen when exposed to the absorbing action of calcium plumbate. The regeneration of the plumbate is effected by the action of air blown into the retorts after the expulsion of the carbonic acid.

In Peitz's patented process, pure carbonic acid is used, by the aid of which the oxygen is expelled at a red heat.

—F. M.

*The Chlorination of Ethyl Alcohol.* M. Altshul and Victor Meyer. *Ber.* **26**, 2756—2759.

THE mixture of products obtained in the manufacture of chloral, consisting of chloral alcoholate, chloral hydrate, chloral anhydride, and trichloroacetal, when subsequently decomposed by sulphuric acid and distilled over calcium carbonate leaves an oil behind in the residual calcium chloride which is volatile with steam. This oil, 2–3 kilos, of which were obtained from 1,000 kilos, of crude chloral, boils between 60–168° C., and yields three fractions on rectification. The first, boiling between 60–90° C., consists of chloroform, which most probably results from the decomposition of trichloroacetic acid in the distillation with steam, since it is not contained in the crude chloral. The second fraction, from 90–140° C., has not yet been examined. The third, from 110°–168° C., contains the ethyl ester of dichloroacetic acid, trichloroethyl alcohol, and probably dichloroethyl alcohol also. The chlorinated alcohols, which are only formed in very small quantity, result in all probability from the direct substitution of the ethyl alcohol, whilst the chlorinated acids are to be regarded as being formed by the oxidation of the corresponding aldehydes and will naturally be converted into their esters in the presence of alcohol.—C. A. K.

*Compounds of Sugars with Iron.* F. Evers. *Ber.* **27**, 474—475.

IRON saccharates similar to those described by Schmidt (*Arch. de Pharm.* 1888, 137), but approximately constant in composition, and free from alkali, may be thus obtained. A solution of 120 grms. of cane-sugar in 1 kilo. of ferric chloride (sp. gr. 1.28) and 2 kilos. of water is quickly stirred into a slight excess of a solution of sodium hydrate (7½ per cent.). The mixture is at once largely diluted with water and the precipitate separated, preferably by means of a filter-press, and washed, first with sugar solution (1:1000), then with water. The precipitate, when dried at a low temperature, forms a red-brown crystalline powder, and appears to be a chemical compound of sugar and ferric oxide (48–49 per cent. Fe), for the former is not removed even by boiling water. This iron saccharate dissolves slowly in a hot, moderately strong solution of cane sugar leaving only a small insoluble residue of ferric hydrate. The solution, on evaporation, yields a brown, amorphous, hygroscopic mass of soluble iron saccharate, which retains its solubility in water (and 90 per cent. alcohol) indefinitely. The soluble saccharates thus obtained differs from the preparations containing alkali, in so far that the iron is not precipitated from its solution by sodium acetate. Moreover, no precipitation occurs when the compound is added to a solution containing hydrochloric acid, salt, and peptone; nor is the iron thrown out, even when a great part of the sugar is removed by dialysis. It is important to note that in the above respects, the preparation in question in no way differs from the alkali-free saccharates made according to Athenstaedt's process (*Ger. Pat.* 52,082). The insoluble and soluble compounds of iron with maltose resemble the corresponding preparations of cane-sugar and may be similarly obtained.—H. T. P.

*Hyoscine.* O. Hesse. *Annalen*, **277** [3], 304—306.

RAEHLMANN believes he has discovered in "Scopolamine" an alkaloid, possessing advantages over hyoscine for inducing *mydriasis*. The author strongly maintains, and indeed demonstrates, that scopolamine is nothing but hyoscine. The conclusions he arrives at, the proofs of which he gives in the text, are:—

1. Hyoscine, discovered by Ladenburg, has in the pure form the composition  $C_{17}H_{23}NO_4$ .

2. Hyoscine yields on decomposition at 60–100° C. as basic product, only *osine*  $C_{11}H_{13}NO_2$ .

3. Scopolamine is really hyoscine, and the scopolamine arising by its decomposition is nothing but osine.

4. Scopolamine hydrobromide is no new mydriatic, but only hyoscine hydrobromide, known since the year 1881.

—W. S.

*The Melting Point of Cocaine Hydrochloride.* Cincónine, &c. O. Hesse. *Annalen*, **277** [3], 308—309.

Messrs. Böhringer and Sons have pointed out to the author that cocaine hydrochloride has no melting point, since it first decomposes and then the *residue* melts (this *Journal*, 1894, 172). On heating for 31 minutes at  $160^{\circ}$ — $161^{\circ}$  C., after 15 minutes the salt caked together, and after 25 minutes intumescence set in. After 31 minutes complete fusion had taken place. The author practically confirms this observation, but considers that since at  $185^{\circ}$ — $186^{\circ}$  C. the intumescence merges itself sharply into the fusion throughout the whole mass,—this point and the precise behaviour thereat, taken together, may be safely adopted in testing the quality of a sample of the hydrochloride. In such case, the cocaine salt should be quickly heated to  $175^{\circ}$  C., and the temperature then be slowly raised.

He also points out that cinchonine, generally considered as melting at  $252^{\circ}$ — $253^{\circ}$  C., also decomposes at that point of temperature, and hence, after a time, changes its melting point. Tropine platino-chloride likewise, instead of melting at  $198^{\circ}$ — $201^{\circ}$ , will melt at  $186^{\circ}$ — $187^{\circ}$ , if heated constantly for a few minutes at this latter temperature.

—W. S.

*The Atropine Alkaloids.* O. Hesse. *Annalen*, **277** [3], 290—300.

RESEARCHES by the author on the belladonna root had demonstrated, that it sometimes contains hyoscyamine alone, though very frequently small quantities of atropine also, and occasionally a new alkaloid, atropamine (this *Journal*, 1891, 158). Schütte furthermore discovered very small quantities of hyoscyne (*Arch. de Pharm.* **230**, 709). Merck maintains that atropamine is identical with the apo-atropine previously prepared by Pesci (*Gaz. Chim. Ital.* **11**, 547; **12**, 287), and he has succeeded in converting his apo-atropine into belladonnine just as the author had done when operating on atropamine (Merck's *Jahresber.* 1892, 3). The principal remaining difference between the two bases, is that whilst apo-atropine with ammonia yields an intense violet colour, is crystallisable, and yields tropine by its decomposition, atropamine exhibits no coloration with ammonia, is uncrystallisable, and by decomposition, after previous conversion into belladonnine, yields no tropine. However, Merling (*Ber.* **17**, 381) and Merck have likewise obtained tropine by the decomposition of belladonnine.

The apparent confusion, if not contradiction, thus engendered, led to further researches by the author, and as result he *firstly* confirms Merck's observation that apo-atropine is really identical with "atropamine" (this *Journal*, 1893, 861). *Secondly*, he demonstrates a closer connection between apo-atropine and hyoscyamine which does much to explain the fact of the occasional appearance of the former in the belladonna root. *Thirdly*, that hyoscyamine becomes converted into atropine, apo-atropine, and belladonnine under conditions more or less existing in the respective method of manufacture. Hence, the possibility that in course of manufacture not only apo-atropine is obtained as a by-product, but also belladonnine. *Fourthly*, whereas during the change of hyoscyamine into atropine and apo-atropine, the tropine group remains intact, this group suffers, during the further change into belladonnine, a change of position, which results through the change of properties of the new base produced. The author's result with belladonnine is now only contradictory of that of Merling, whereby tropine is produced by the decomposition of belladonnine. The author can only explain this on the supposition that the bellatropine on long boiling with alcoholic baryta solution is probably reconverted into tropine. Purified belladonnine obtained in the manufacture of atropine, heated to  $140^{\circ}$  C. with eight parts of fuming hydrochloric acid, yielded only traces of tropine, but much bellatropine. Atropine, on heating with hydrochloric acid at  $140^{\circ}$  C., yields tropine but no bellatropine. Thus, then, the conversion of atropine into belladonnine depends upon a conversion of the tropine residue into a bellatropine residue, and consequently

apo-atropine bears the same relation to tropine that belladonnine bears to bellatropine. Kraut, indeed (*Ber.* **26**, 1084), by 16 hours' heating of tropine with fuming hydrochloric acid, seems to have actually obtained bellatropine.

—W. S.

*Pereira Alkaloids.* O. Hesse. *Annalen*, **277**, 300—302.

THE investigation of Pereira hark demonstrated that it contained three alkaloids—Geissospermium,  $C_{19}H_{24}N_2O_2$ ,  $H_2O$ ; Percirine,  $C_{19}H_{24}N_2O$ , and a base which separates from its ethereal solution in granular crystals. The latter is more soluble in ether than geissospermium, and remains therefore in the mother-liquors when geissospermium is crystallised from ether. It is soluble in concentrated nitric acid, producing a purple-red coloration, and in so far resembles both geissospermium and percirine. The "geissospermium" of Freund and Fauvet (this *Journal*, 1893, 618) seems to be identical with this alkaloid. The author, to avoid confusion, now terms Freund and Fauvet's "geissospermium," the "new alkaloid," and commences by observing that it is considerably more soluble in ether than geissospermium. Equally concentrated solutions of both alkaloids in dilute sulphuric acid, agitated with excess of ammonia and equal volumes of ether, yield—

- (a) Geissospermium at once in small needles, terminating in domes;
- (b) "The new alkaloid" only after some minutes, and crystallised either in rhombic plates exhibiting gradually other faces, or else in granular crystals with many faces.

Geissospermium crystallised from alcohol or ether, contains a molecule of water of crystallisation, which it loses at  $100^{\circ}$  C., and agrees with the formula  $C_{19}H_{24}N_2O_2$ .

The "new alkaloid" contains no water of crystallisation, and has the formula  $C_{22}H_{28}N_2O_4$  (Freund and Fauvet). Geissospermium melts at  $160^{\circ}$  C., whilst the new alkaloid melts at  $189^{\circ}$  C.; moreover the former dissolves in concentrated nitric acid with a purple-red colour, becoming paler after a few hours; whilst the latter yields the same colour, which does not become paler. Geissospermium dissolves in sulphuric acid containing ferric oxide in solution, with a beautiful blue colour, whilst the "new alkaloid" forms a colourless solution. Similarly, both alkaloids behave with sulphuric acid containing molybdic acid, but the colourless solution of the "new alkaloid" on heating becomes intensely purple-red. The former with hydrochloric acid, yields an uncrystallisable salt easily soluble in water or hydrochloric acid; the latter gives at once beautiful crystals of hydrochloride. The geissospermium hydrochloride gives in aqueous concentrated solution with potassium sulphocyanide, an amorphous precipitate, whilst the hydrochloride of the "new alkaloid" gives a milky precipitate, consisting of white needles concentrically grouped together. Geissospermium easily dissolves in dilute sulphuric acid, and yields a normal salt, crystallising in delicate white prisms. The "new alkaloid" is but little soluble in such an acid; at the same time the undissolved portion is converted into sulphate, only with difficulty soluble at ordinary temperatures in dilute sulphuric acid. The sulphate forms granular crystals, dissolving in the mother liquor on heating, and recrystallising on cooling.—W. S.

*The Alkaloids of the Bark of the Pomegranate Root.* G. Ciamician and P. Silber. *Ber.* **26**, 2738—2753.

THIS paper contains the continued investigations of the authors on the alkaloid "Pseudo-pelletierine," first isolated by Taurer, from the bark of the pomegranate root. It is proposed to substitute the name "*Granatoline*" for the above, so as to allow of a more simple nomenclature for its derivatives. The base is closely related to tropine, and yields a series of corresponding derivatives, as is shown by the following table:—

Granatoline.....	$C_{11}H_{15}NO$	Tropine.....	$C_8H_{13}NO$
Granatoline.....	$C_{11}H_{15}NO$	Tropamine.....	$C_8H_{13}N$
Granatamine.....	$C_{11}H_{15}N$	Hydrotropine.....	$C_8H_{13}N$
Granatamine.....	$C_{11}H_{15}N$	N-hydrotropine.....	$C_7H_{13}N$
Nor-granatoline...	$C_{10}H_{13}N$		

These bodies result successively by the reduction of granatoline; granatoline yields a hydriodide corresponding to that of tropine. Granatoline is regarded as the homologue of tropine, but the hitherto ascertained facts regarding the former are too incomplete to allow of a constitutional formula being assigned to it. The properties of granatoline are given in previous papers (Ber. 25, 1698, and 26, 156; this Journal, 1892, 705); in the present communication those of the above derivatives are described. The examination of the other alkaloids associated with granatoline especially pelletierine, are now under investigation.

—C. A. K.

*Compounds of the Citral (Geraniol) Group.* F. Tiemann and F. W. Semmler. Ber. 26, 2708—2729.

*Citral*, the aldehyde contained in lemon oil and in oil of lemon-grass, is an almost colourless liquid, slightly soluble in water, readily in alcohol and ether and which distils at 120°—122° C., under a pressure of 23 mm. It is best isolated from the oil by means of its crystalline double compound with acid sodium sulphite. Citral is optically active; on reduction it yields the alcohol geraniol, which is optically inactive. Closely related to geraniol are a number of optically active alcohols having the same formula,  $C_{10}H_{18}O$ , all of which yield citral on oxidation. These include *coriandrol*, the alcohol of coriander oil; *linalool*, from linaloe oil (from *Bursera delpechiana*); and *rhadinol*, the alcohol obtained from rose-oil by Eckart (Ber. 24, 4209; this Journal, 1892, 265). The relationship of these alcohols are discussed. The oxime, hydrazone, anilide, and nitrile derived from citral are described. The last yields geranic acid,  $C_{10}H_{16}O_2$ , upon treatment with alkali, which acid is also formed by the action of moist silver oxide upon citral. When citral is oxidised at 0° C. with chromic acid, only a minute quantity of geranic acid is obtained, methylheptylene ketone,  $C_8H_{14}O$  and an acid, which yields the ketone on distillation, being the essential products. Geraniol oxidised under similar conditions yields the same products. The remainder of the paper deals with a number of cyclic compounds, obtained by the action of sulphuric acid upon geraniol derivatives and which bear upon the constitutional formulae of citral and of geraniol.—C. A. K.

*Determination of Oil of Turpentine in Alcohol.*

J. Perl. Chem. Zeit. 17, 1851.

See under XXIII., page 427.

*The Estimation of Saccharine in Presence of Salicylic Acid.* Hairs. J. de Pharm. d'Angers.

See under XXIII., page 424.

## PATENT.

*A new Medicinal Preparation for the Curative Treatment of Leprosy, Cancer, Eczema, and other allied Diseases.* W. Watson, London. Eng. Pat. 8493, April 27, 1893.

This preparation, for internal use, consists of a decoction of an Indian plant, *Farnaria parinflora*, known in the Punjab as "Papperah," either in the dry or fresh condition.

—J. G. W.

## XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

### PATENTS.

*Improved Silver Haloid Emulsions for Photographic Purposes.* W. H. Prestwich, Tottenham. Eng. Pat. 5517, March 14, 1893.

This invention relates to sensitive silver emulsions for coating glass, films, or paper for photographic purposes, the improved emulsion, in the case of negatives, preventing solarisation and halation; in the case of transparencies imparting a ground-glass effect; and in the case of prints on paper or opal glass, producing a matt surface. These results are obtained by using, in conjunction with gelatin, a proportion of an amylaceous substance such as starch, arrow-root, corn or rice flour, say 3 parts of gelatin to one of starch.—E. G. P. T.

*Improvements in Processes of Making Transparent Photographs on Glass.* C. A. Allison, London. From F. B. Forster and G. G. Rockwood, both of New York, U.S.A. Eng. Pat. 6501, March 28, 1893.

This process consists in printing the positive image in a metallic oxide from the negative upon a medium which has been surfaced with a mixture of the materials constituting the sensitive film and said metallic oxide; then transferring said print to, and developing it upon, a temporary support; then transferring the print and rendering it insoluble upon the surface of a transparent glass plate; then coating the print with a vitreous flux which fuses at a temperature between 600 and 700 F.; and lastly, subjecting the glass plate bearing the print and its flux, to a degree of heat sufficient to fuse the flux.—E. G. P. T.

*An Improved Method of Preparing Pigment Paper for Photographic Printing.* W. White, Paddington. Eng. Pat. 824, January 13, 1894.

By this method the usual operations of the carbon or pigment printing process may be performed in any ordinary apartment and in ordinary daylight. A paper or other flexible material is selected, for supporting the pigment and gelatin compound, which is opaque or suitably coloured, so as to transmit only non-actinic light. The supporting tissue is coated with the pigment compound and dried. The sensitising is performed in the usual way, and when sufficiently flaccid, the paper is taken out and laid on a sheet of zinc, or other smooth and opaque material, the excess of solution being removed by a squeegee; the whole is then placed aside in a current of air to dry.

—E. G. P. T.

## XXII.—EXPLOSIVES, MATCHES, Etc.

*A New Method of Estimating Yellow (Ordinary) Phosphorus.* Julius Töth. Chem. Zeit. 17, 1244.

See under XXIII., page 420.

### PATENT.

*An Improved Igniting Composition for Matches.* J. M. Meissner, Vienna, Austria. Eng. Pat. 6775, March 30, 1893.

This invention essentially consists in employing aluminium as an ingredient of igniting composition for matches. The composition consists of a suitable adhesive substance and potassium chlorate, potassium, barium, or strontium nitrates, and finely pulverised aluminium; with or without the addition of iron filings or granular aluminium.—W. M.

## XXIII.—ANALYTICAL CHEMISTRY.

## APPARATUS, ETC.

1. *New Thermometer for High Temperatures.* E. C. C. Baly and J. C. Chorley. Ber. 27, 470—471.

THE appearance of this instrument is precisely that of an ordinary mercurial thermometer, but instead of mercury it contains the liquid sodium-potassium alloy. The boiling point of the alloy is about  $760^{\circ}\text{C}$ ., whilst its freezing point is  $-8^{\circ}\text{C}$ ., and hence the thermometer charged with it possesses the wide range of  $-8^{\circ}\text{C}$ . to  $650^{\circ}\text{C}$ . For the sake of convenience, however, the graduation only commences at  $200^{\circ}$ , so that the ordinary dimensions of a mercurial thermometer are not materially exceeded. To this end the tube has a bulbous expansion blown upon it, at a distance of about 12 cm. above the bulb forming the alloy reservoir. The glass is of the most infusible quality ("Resistenz Glas"), capable of withstanding a red heat. The space above the alloy is filled with pure nitrogen under a pressure such that when the reservoir is red hot, and thus somewhat soft, the interior pressure will be about equal to the external atmospheric pressure. Thus, alteration in the form of the reservoir is avoided.

The thermometer is not graduated until it has withstood successfully the application of a red heat for 30 hours. The fixed points, for the higher graduation, are established by immersing the instrument in the vapours of boiling sulphur and other substances. Only the reservoir and 9 cm. of the tube are heated, since the coefficient of expansion of the alloy increases with the temperatures. In this way the error of the unprotected thread is compensated. Thus, then, in using the thermometer, not more than 9 cm. of the tube should be exposed to the heat, and special care should be taken that the bulbous expansion, already referred to, is not heated.—W. S.

## Simple Extraction Apparatus. W. Büttner. Zeits. ang. Chem. 1893, 634—635.

THE author describes an extraction apparatus which can be easily made in the laboratory, and which possesses the additional advantage that only one cork is required. The apparatus is represented in the accompanying figure. The outer tube consists of an ordinary rather thick-walled test tube, 150—160 mm. long, and 30—35 mm. wide, contracted slightly about 60—70 mm. from the bottom. In the upper part is placed a somewhat narrower test tube, and into this dips a siphon, as shown in Fig. 1. The siphon is made by

Fig. 1.

Fig. 2.

Fig. 3.

drawing out a piece of glass tubing before the blow-pipe until its bore is about 1.5—2 mm., and then bending it as shown in Fig. 2, or preferably as in Fig. 3, which allows of its easy introduction into the inner test tube.

The substance to be extracted is placed in a cartridge of filter-paper, which fits loosely into the inner tube. The extract is obtained in the lower part of the wide tube, in which it may be evaporated to dryness and weighed.—J. S.

## A Colorimeter with Lummer-Brodhun Prism System.

H. Küss. Zeits. f. anorg. Chem. 5, 1893.

IN colorimetric investigations generally, the object is to determine as accurately as possible the point when two solutions, &c., being compared, are equal in point of colour and brightness. In practice, the solutions contained in cylinders, &c. are viewed simultaneously, side by side, by transmitted light, in the field of a lens or telescope. The delicacy of the method depends largely on the degree of proximity of the two areas to be compared, and is greatest when the boundary between them is a "mathematical" line. The contrivance chiefly used for this purpose (Fig. 1),

Fig. 1.

consisting of two reflecting prisms  $p^1$  and  $p^2$  and an eyepiece  $L$ , suitably placed above the cylinders, has been generally found somewhat unsatisfactory, owing to the fact that the line of demarcation ( $t$ ) between the two halves of the field has an appreciable width, thus impairing the accuracy of the results. This difficulty may be overcome by employing the modified prism system (Fig. 2) devised

Fig. 2.

by Lummer and Brodhun for photometric purposes. It consists of two prisms, an ordinary total reflecting prism  $B$ , and a spherically-faced prism  $A$ , of which only the central portion  $rs$  is ground flat and placed in optical contact with  $B$ . An eye placed at  $O$ , receives from the direction  $L^1$  only the direct rays passing through the area of contact  $rs$ ; from the direction  $L^2$  only the rays reflected by the surfaces  $er$  and  $sb$ , and will therefore, in general, perceive a sharply defined, bright or dark, elliptical spot, surrounded by a uniform field. When the direct and reflected rays are of equal intensity, the illumination of the field is uniform all over, and the central spot completely disappears. The general arrangement of the apparatus for colorimetric purposes is indicated in Figs. 3 and 4. Two subsidiary prisms,  $p^1$  and  $p^2$ , are employed, which reflect the light from the cylinders,  $C^1$  and  $C^2$ , containing the liquids to be compared, into the component parts of the main prism,  $A$ ,  $B$ , from which it passes into the eye-piece  $L$ .

Fig. 3.

Fig. 4.

Concerning the delicacy of the new colorimeter, it appears that, for photometric purposes, the Lummer-Brödhun prism system is about three times as sensitive as the ordinary arrangement, in which the central line of the field is not eliminated. —H. T. P.

#### PATENT.

*Improvements in the Method of and Apparatus for Determining the Density of Gases.* G. Frères and M. Meslans, both of Paris, France. Eng. Pat. 70, January 1, 1894.

See under I., page 378.

(Also this Journal, 1894, 64.)

#### INORGANIC CHEMISTRY.—QUALITATIVE.

*Paranitrophenol Sodium as Acid Indicator in Testing Boiler Feed Water for the Presence of Magnesium Chloride.* A. Goldberg. 12. Ber. d. naturw. Gesellsch. z. Chemnitz, 1893, 68.

EXPERIMENTS on the large scale having proved the usefulness of this indicator in checking the efficiency of the water purification process by means of caustic soda, the author made some trials on a small scale with a view of ascertaining the applicability of this method to the preliminary testing

of boiler feed-water. The object of the test is to find out whether the water is likely to acquire an acid reaction when heated in the boiler under pressure.

A tube made of wrought-iron, by boring out a solid block, and another of copper closed with a gun-metal screw-cap, were used in the experiments. The iron tube at first proved unreliable, a solution of the indicator in distilled water being decolorised at a temperature of from 150 to 160° C. After repeated use, however (and consequent formation of a protective layer of oxide), solutions of the indicator 1 to 50,000 and 1:100,000 remained intact at 165° C. The presence in the water of  $\frac{1}{100,000}$  and even  $\frac{1}{1,000,000}$  part of magnesium chloride caused complete decolorisation. The results obtained with the copper tube were different. A 1:50,000 or 1:100,000 *p*-nitrophenol-sodium solution remained unaffected after the addition of a small quantity of magnesium chloride (from 0.1 to 1 gm. per litre) and heating to 180° C. The hydrochloric acid which may have been formed by dissociation, appears to have recombined on cooling. No change of the colour was observed after the addition to the water (with or without MgCl<sub>2</sub>) of various neutral soluble reducing agents and of nitrates. The simultaneous presence of some organic substances, such as sugar, glue, &c., however, caused a reduction, which also took place in the pure solution of the indicator after the introduction of metallic zinc, iron, or powdered spathic iron ore.

It may be concluded from these results that the iron-tube method is a reliable means of testing boiler feed-water with the indicator; that the changes the *p*-nitrophenol sodium might suffer in the boiler itself by secondary reactions, are insignificant; and ultimately, that water causing decolorisation of the indicator in the copper tube may be considered to possess a pronounced tendency to become acid. —F. M.

#### INORGANIC CHEMISTRY.— QUANTITATIVE.

*Preparation of Pure Potassium Iodate for Volumetric Analysis.* M. Groger. Zeits. ang. Chem. 1894, 1, 13.

THE salt can be conveniently prepared by dissolving 40 grms. of pure potassium permanganate in hot water, adding 20 grms. of potassium iodide dissolved in a little water, and heating the mixture on a boiling water-bath for 20–30 minutes, then dropping in alcohol until the red colour due to excess of permanganate is discharged, and filtering the product. The reaction which occurs is represented by the equation—

The filtrate, alkaline with caustic potash, is treated with acetic acid until it has a perceptibly acid reaction; it is then concentrated to about 50 cc. and allowed to cool. The mother-liquor is poured off the granular crystals of potassium iodate which have formed, and the salt is then repeatedly washed with strong alcohol and allowed to dry. The acidification of the filtrate from the oxidised liquid is essential, since, unless this precaution be observed, six or seven crystallisations are necessary to free the iodate from caustic potash, which adheres obstinately to it. The product is thereby reduced to 40–50 per cent. of the theoretical amount, whereas when acetic acid has been used 90–95 per cent. of the calculated quantity of potassium iodate is obtained. Free alkali cannot be removed by washing with alcohol, as some potassium carbonate is always formed by contact with the air, and, being insoluble in alcohol, remains with the iodate. Potassium acetate, on the other hand, is readily removed by treatment with alcohol. The potassium iodate prepared in this manner is perfectly pure, has a neutral reaction, and remains colourless when acidified with dilute sulphuric acid and allowed to stand. It can be used for standardising thiosulphate and acids in the manner described by the author (Zeits. ang. Chem. 1890, 285). —B. B.

\* The quantities given in the article quoted are ten times those that should be used, the omission of a decimal point having occurred.

*S. Ium Thiosulphate for Iodometry.* C. Meineke. Chem. Z. it. 19, 33—34.

Pure sodium thiosulphate forms a convenient means of standardising iodine solutions and titrating iodine; but although the salt is easily obtained sufficiently free from saline impurities, it generally contains a slight excess of water, probably enclosed in the crystals as mother-liquor; so that the quantity of actual  $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$  present is only 98—99 per cent. It can be entirely dehydrated *in vacuo* over sulphuric acid ( $\text{Na}_2\text{S}_2\text{O}_3 = 99.9—99.95$  per cent.); but the product is extremely hygroscopic, so that it cannot be kept in ordinary stoppered bottles without alteration. Drying the powdered crystals by pressure in blotting-paper does not remove adherent moisture as thoroughly as rubbing in a mortar with strong alcohol, sucking off the liquor, washing with absolute alcohol or ether, and drying in filter-paper; the product thus obtained from a pure salt free from sulphate may be kept for years without alteration; thus a sample containing, in 1888, 99.90—99.91 per cent. of  $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ , gave, in 1891, 99.94 per cent.; in 1892, 99.93 per cent.; and in 1893, 99.92—99.94 per cent. Precipitation of a concentrated aqueous solution with alcohol gives crystals enclosing mother-liquor, so that only about 99 per cent. of true pentahydrated salt is present.

—C. R. A. W.

*The Estimation of Iodine in the Presence of Bromine and Chlorine.* M. Groeger. Zeits. f. ang. Chem. 1894, 52.

ALKALINE iodides, in a neutral or alkaline solution, are completely oxidised into iodates by the action of potassium permanganate, whilst bromides or chlorides suffer no alteration under these conditions. Reinize proposed to utilise this reaction for the estimation of iodine in the presence of bromine and chlorine, by titration with permanganate, according to the equation—

MacCulloch showed this method to be deficient, owing to the precipitate of potassium manganate, formed during the process, and containing less oxygen than that required for manganic peroxide. The author proposes to estimate the amount of iodic acid formed by this oxidation iodometrically. For this purpose, the substance to be analysed is weighed, dissolved, and diluted to a definite volume with water. An aliquot part of this solution, containing at most 50 mgrms. of iodine, is heated on the water-bath in a flask, excess of permanganate solution (1 : 25) added, and this excess, after prolonging the heating for some minutes, at the end of which the strong red coloration of the liquid should have been maintained, is then removed, by the addition of a few drops of alcohol. After the subsidence of the precipitate formed in the liquid, the latter is filtered and the residue on the filter well washed. All the iodine is now contained in the filtrate in the form of potassium iodate. After cooling, 0.5 gram. of potassium iodide is added, and the solution is acidulated with hydrochloric acid. Iodine separates out according to the equation—

and is then estimated by means of 1/10 N-thiosulphate, using starch solution as an indicator. 1 cc. of the thiosulphate represents 2.109 mgrms. of I contained in the titrated solution. The trustworthiness of the method was demonstrated by applying it to solutions which had been beforehand standardised gravimetrically. Presence of ammonia vitiates the results owing to the formation of nitrites during the process of oxidation. In this case it is necessary to expel the ammonia before oxidising by boiling the solutions with a small excess of caustic potash. Too great an excess of caustic alkali should be avoided as preventing the complete reduction of the permanganate. The method may also be employed for the assay of commercial iodine, which frequently contains chlorine, bromine, and cyanogen.—C. O. W.

*Valuation of Fuels.* F. Fischer. Zeits. ang. Chem. 1893, 677—679.

The author points out that it is only in cases where coal or coke is used for reducing or smelting purposes that the estimation of the total sulphur is important. In other cases it is sufficient, and better, to determine the amount of sulphur which is converted into sulphurous or sulphuric acid on combustion. For this purpose he recommends the apparatus shown in the figures.

A weighed quantity of coal or coke (0.5—1.0 gram., according to the amount of sulphur contained in it) is placed in the combustion tube in the platinum boat *p* and ignited in a current of oxygen introduced at *o*. The other end of the tube *a* is packed with asbestos or pumice stone, which is kept at a red heat during the operation. The system of bulbs contains 10—20 cc. of a pure solution of peroxide of hydrogen, which serves to oxidise the sulphurous to sulphuric acid. After the combustion is at an end, the contents of the bulbs are transferred to a beaker and titrated with deci-normal potash solution. The second figure shows another system of bulbs, in which the drawn-out end of the combustion tube dips into the peroxide of hydrogen. By weighing the platinum boat afterwards, the amount of ash contained in the coal may be determined.

The author also points out that many thermo chemical calculations may be much simplified by making use of the number 22.3 (the volume in litres at standard temperature and pressure occupied by a gramme-molecule of gases and vapours). Reference is also made to one of Niehl's high-temperature thermometers, which enables temperatures to be measured up to 560° C.—J. S.

*A New Method of Estimating Yellow (Ordinary) Phosphorus.* Julius Toth. Chem. Zeit. 17, 1244.

The method is intended for the purpose of ascertaining the quantity of phosphorus in mixtures containing also phosphoric acid, and consists in the extraction with carbon bisulphide, precipitation of the phosphorus in solution by means of silver nitrate, oxidation of the silver phosphide formed with dilute nitric acid, and precipitation of the phosphoric acid in the usual manner.—F. M.

*Volumetric Estimation of Lead in Tin Solutions or Platings.* P. Bayrac. Journ. Pharm. Chim. 1893, 5, Sér. 28, 500.

A STANDARD solution of di-sodium phosphate is employed in this method. Lead phosphate being soluble in mineral acids, sodium acetate is added to the solution to be tested, to counteract this effect. An excess of di-sodium phosphate is added, which is titrated back with a standard solution of lead nitrate, potassium iodide being used as an indicator. The reaction taking place in the process is expressed by the following equation:—

—F. M.

*A Simple Method for Determining Foreign Metals in Commercial Copper.* W. Hampe. Chem. Zeit. 17, 1691.

THE following method will be found much quicker than that previously described by the author. 25 grms. of the copper are placed in a large beaker with 200 cc. of water, 100 cc. of pure concentrated sulphuric acid, and 45–46 cc. nitric acid of sp. gr. 1.210. The solution proceeds rapidly and quietly on heat being applied, and when all the copper is dissolved, about 200 cc. of water are again added, to prevent crystallisation on cooling. The solution is clear except when lead, antimony, or bismuth are present; in such cases the solution must be filtered, and the precipitate separately analysed. The clear solution is heated to 40° C., and a brisk stream of sulphurous acid is passed through it, which quickly reduces the small excess of nitric acid present; this stream should be continued until the solution smells strongly, when, if silver be present, turbidity will arise, owing to a partial precipitation of metallic silver, which may be disregarded when no "wet" silver determination is to be made; or it may be rendered complete by adding a few drops of HCl and setting aside for 24 hours in a 2-litre flask. The mixture of Ag and AgCl is then collected on a small filter, which is treated with hot fuming nitric acid, and the silver is subsequently determined as chloride in the usual way. Such determinations have been found to agree very well with the results of dry methods.

The solution containing suspended particles of metallic silver, or the filtrate from the last operation, as the case may be, is now treated, while cold, with chemically pure sulphocyanide of copper, while a stream of SO<sub>2</sub> is again passed through it. The sulphocyanide must not, however, be in excess; indeed it is better to leave a little copper in solution since it does not interfere with the subsequent operations. A solution of known strength is therefore used, 500 cc. of which will precipitate 25 grms. copper, and this is added by degrees, so as to leave a very little copper in solution. The gas-leading tube is then withdrawn, water is added until the flask is filled up to the mark, and the whole is well mixed and left to rest for a time, when it is filtered through a dry filter into a dry beaker. From the filtrate, a known volume, say 1,800 cm., is taken, the SO<sub>2</sub> is driven off, and sulphuretted hydrogen is passed with the usual precautions so as to precipitate the metals of the arsenic group, which, when present, may be separated and separately determined by the ordinary methods. The same may be said of the following precipitate of nickel, iron, &c., by means of sulphide of ammonium.

In calculating the analysis, the volume of the copper sulphocyanide precipitate must be taken into account. When the copper present amounts to 25 grms. it occupies a space of 15.983 cm., leaving 1984.017 cm. for the true volume of solution in the 2-litre flask. Details are given of the method of calculation and of comparative tests, giving very close results, and the author states that analyses formerly occupying five or six weeks can now be performed in about eight days.—J. H. C.

*The Reliability of the Principal Methods of Determining Total Carbon in Iron.* Göttig. Abhandl. d. Vereins. z. Beförd. d. Gewerbeleisses. 1893, 3, 321.

THE author arrives at the following conclusions:—

I.—The direct estimation of carbon by combustion of the iron in a current of oxygen is, in no case, to be recommended. The method nearly always yields low results, chiefly owing to the difficulty experienced in recognising when the process is completed; and partly because the oxide of iron formed occludes particles of carbon, which thus escape combustion.

II.—The wet combustion process—with chromic and sulphuric acids—may be directly applied (*i.e.*, without previous separation of the carbon) in every instance. There is, however, a possibility of small quantities of hydrocarbons being formed, especially when the sulphuric acid employed is dilute. It is advisable, therefore, to use a good excess of chromic acid (12–15 times the weight of the iron), and to include a tube of glowing copper oxide and a drying apparatus before the absorption bulbs. This is especially necessary in the case of samples containing

much combined carbon. In practice the method is advantageously applicable to graphitoid or manganous irons (Spiegeleisen, ferromanganese). Indeed, for this purpose, the author condemns all dry combustion processes, since the graphite, even when previously separated from iron, is exceedingly difficult to burn. In the case of samples only available in the shape of coarse grains or large pieces, it is well to dissolve out the iron prior to combustion. For this purpose Weyl's electrolytic process is generally suitable, the electrode being surrounded by fine platinum wire-gauze in order to prevent loss of carbon. For the estimation of total carbon in iron free from graphite, the chromic acid method is most convenient when only single determinations are to be made; but when a series of samples are to be analysed, Wohler's chlorine process is preferable. A number of samples (8–10) may be simultaneously treated with chlorine, the residues being afterwards burnt in a stream of oxygen.

III.—In methods involving the solution of the iron in copper sulphate, &c., there is no need to separate the precipitated copper from the carbon, if the latter is to be burnt in the wet way. Otherwise this must be done, for the same reason as under I.

As regards the estimation of graphite in iron and steel, the author makes the following observations:—

1. Thorough boiling of the material with nitric or hydrochloric acid, renders subsequent washing of the residue with potash, alcohol, and ether unnecessary, and gives better results than when the boiling is omitted and washing resorted to.

2. Compared with hydrochloric acid, the use of nitric acid easily leads to low results.

3. Nitric acid is to be preferred to hydrochloric acid, because by its means a residue free from combined carbon is more readily obtained.—H. T. P.

*Determination of Carbon in Iron and Steel.* W. Hempel. Zeits. ang. Chem. 1894, 1, 22–24.

THE method of determining carbon in iron by solution in chromic acid mixture is imperfect, from the fact that hydrocarbons are evolved. This defect can be removed by the addition of mercury. 0.5 gm. of the iron is treated with 2.3 grms. of mercury and a mixture of chromic acid, sulphuric acid, and water in a partial vacuum, and the atmosphere thus obtained, consisting of air, oxygen, and CO<sub>2</sub>, is drawn over into a gas-analysis apparatus, and the CO<sub>2</sub> determined. The apparatus used is shown in the figure.

A is a measuring tube of a capacity of 150 cc., for the reception of the gas to be analysed; B is a correction tube to save calculations for alterations of temperature and pressure; and C is a manometer connected by one limb with the gas burette and by the other with the correction tube. The burette and correction tube are enclosed in a common water-jacket. A round-bottomed flask at the right of the figure serves for the solution of the iron; it is provided with a condenser and a stoppered funnel. The following reagents are required:—(1.) *Chromic Acid Solution*.—Commercial chromic acid is generally sold in bottles luted with paraffin wax, particles of which may obtain access to the interior of the bottle and cause an error. The acid should therefore be prepared by dissolving 300 grms. of potassium bichromate in 500 cc. of water and 420 cc. of strong sulphuric acid. When solution is complete the mixture is allowed to stand for 12 hours, the clear solution is poured off, from the potassium bisulphate, which crystallises out, and this salt is washed with 10–12 cc. of water. The solution is warmed to 80–90° C., and treated with 150 cc. of strong sulphuric acid and sufficient water to redissolve any chromic acid that may separate. The solution is concentrated until a crystalline crust forms on the surface, and is then set aside for 12 hours, after which the chromic acid which separates is collected on a platinum filtering-cone by the aid of the pump. Two further crops of crystals may be obtained on again concentrating. The temperature of concentration should be moderate lest the chromic acid be attacked by the sulphuric acid. 100 grms. of the chromic acid thus prepared are dissolved in 300 grms. of water and 30 grms. of sulphuric acid of sp. gr. 1.704, the resulting solution having a specific gravity of 1.2, which should not be exceeded, as otherwise too much oxygen will be given off during the solution of the steel.

(2.) *Sulphuric Acid*.—This should have a specific gravity of 1.704 at 16° C., corresponding with a content of 78 per cent. of  $\text{H}_2\text{SO}_4$ . It is prepared by mixing 1,000 cc. of the strongest sulphuric acid (not necessarily pure) with 500 cc. of water and 10 grms. of chromic acid. The mixture is heated for an hour on the sand bath. The burner is then removed and air blown through the liquid for five minutes to expel any  $\text{CO}_2$  that may have been formed. Seeing that the acid is somewhat concentrated by the heating it is diluted with water to the right specific gravity. The strength should be exact within 1–2 per cent.

The actual analysis is carried out by weighing 0.5 grm. of iron very exactly into the solution flask, adding 2.3 grms. of mercury from a small pipette, exhausting the flask by connecting *k* with the water pump, placing 30 cc. of the chromic acid solution in the funnel *o*, and allowing it to run into the flask by cautiously lifting the tube *m* from the seat into which it is ground at the bottom of the funnel. The contents of the flask are heated to boiling point by a small flame, and 120 cc. of the sulphuric acid prepared as described above allowed to run in through the funnel, and the boiling continued for 30 minutes. Connection with the gas burette is made when sufficient  $\text{CO}_2$  has been evolved to prevent any risk of mercury being sucked back into the solution flask. This is usually the case after the addition of the sulphuric acid. At first only  $\text{CO}_2$  is given off, but as the temperature rises oxygen is also evolved. When the reaction is complete the burner is removed, the funnel filled with distilled water, and allowed to run gently into the flask, until the whole of the gas has been driven over into the burette. Should there not be enough gas to reach to the graduated portion of the burette air is admitted until the level of the mercury has fallen to the proper point. The determination of the  $\text{CO}_2$  is then proceeded with in the usual way.—B. B.

#### *The Determination of Phosphorus in Coal and Coke.* J. Lynchenheim, Swedeland, Pa. Eng. and Mining J., 1894, 222.

In connection with the manufacture of special Bessemer pig, containing 0.030 per cent. or less of phosphorus, it was found that the phosphorus in anthracite varied so greatly that it was necessary to sample and analyse each truckload. This, of course, in addition to routine work,

involved a considerable amount of extra trouble, and some experiments were made, with the view of cutting down the time and labour of the determination to a minimum. As there seemed to be no question that all the phosphorus is to be found in the ash, the old method of fusing 5 grms. of coal with 10 grms. of sodium carbonate, and 40 grms. of potassium nitrate was not tried. It involved too much attention in preventing the fused mass from overflowing the crucible. The author concludes: "I had been under the impression that fusion of the ash or residue was necessary in all cases; but wishing to ascertain exactly what proportion was dissolved out by hydrochloric acid, and what remained in the residue, I tried the experiment of treating the ash exactly like an ore, transferring it to a 5-inch crucible; adding 40 cc. of strong  $\text{HCl}$ ; evaporating to 10 cc.; then adding 40 cc. of nitric acid (specific gravity 1.42) and evaporating until all brown fumes had passed off and the solution contained about 20 or 25 cc. The nitric acid solution has a strong tendency to "bump;" and care must be taken to keep the contents of the crucible in motion. The results showed that the phosphorus was almost completely soluble in hydrochloric acid and only a trace remained in the residue. This, then, was a solution of the problem by which results could easily be obtained in from an hour to an hour and a half, with little labour and attention on the part of the operator. It is just as satisfactory and gives just as concordant results as the longer methods.

"In all this work we have been using a very simple arrangement, by which the combustion of the carbon was considerably hastened. In fact, it was found much more satisfactory than the large fusion crucibles we had previously employed. Its comparative cheapness enabled us to run six analyses at a time, and also did away with the expensive necessity of laying in a supply of large crucibles. It consists of a boat 2 inch square and  $\frac{1}{2}$  inch deep, made from 0.002 platinum foil. Care should be taken in making the boats that the corner flaps fit tightly, so that none of the ash will be lost by getting into the interstices. A tripod, Erdmann chimney, and two pieces of thin platinum wire complete the arrangement. The wires should be so bent as to be about  $\frac{1}{2}$  inch below the top of the chimney. The heat applied for the first five minutes should be a low red, in order that none of the coal shall be lost in the escape of the volatile matter. After that the gas should be turned on full, and a bright red heat maintained. It is not necessary that the sample should be ground very finely. By constant stirring we have effected the combustion of the carbon in half an hour, and with an occasional stirring it should never take more than an hour."

#### *Valuation of Ground Phosphatic Slags.* E. Wrampelmeyer. Landw. Versuchsst. 1893, 43, 183.

A MICROSCOPICAL examination of the sample reveals the presence of natural phosphates through the light colour and the rounded outline of the single grains. In suspicious cases the loss of weight on ignition, the specific gravity and the solubility in water are ascertained. These tests may be followed by the determination of the solubility in citric acid according to Loges and Petermann.

For the determination of the specific gravity the use of a small strong glass vessel of from 8 to 10 cc. capacity is recommended. This is filled with the powder by gentle knocking until no further consolidation takes place. The subsequent operations do not require description.

The amount of soluble matter is estimated in 2 grms. of substance, previously well ignited (but not fritted) in a platinum dish, by the loss of weight brought about by repeated boiling with water and washing on a filter until the filtrate no longer shows an alkaline reaction or leaves a stable residue on evaporation.

Loges' method of estimating the phosphoric acid soluble in citric acid is best carried out in the following manner:—1 grm. of the sample is digested for 12 hours at a temperature of from 50 to 70° C. with 150 cc. of a 5 per cent. solution of citric acid, 100 cc. of water are then added; the mixture is boiled for 1 minute and after cooling made up to 500 cc. Of the filtered solution 250 cc. are reduced by

evaporation to about 50 cc. mixed with 13 cc. of 5 per cent. citric acid solution and neutralised with ammonia. The phosphoric acid is precipitated by the addition of 25 cc. magnesia mixture, and one-third of the total volume of 10 per cent. ammonia, allowing the liquor to stand for at least two hours.—F. M.

### ORGANIC CHEMISTRY.—QUALITATIVE.

*The Poisonous Action of Martins Yellow, and its Detection.* D. Vitali. Boll. chim. farmac. 1893, 32, 738.

MARTINS yellow, often used as a food-colouring, may be detected in the urine by the following methods:—

1. The urine, slightly acidified by hydrochloric acid, is shaken up with ether. A portion of the ethereal layer is shaken with caustic potash solution, the alkaline solution then acidified with hydrochloric acid and warmed, some strands of white wool, free from fat and mordanted with alum solution, are now placed in it. The wool is coloured yellow in the presence of as little as  $\frac{1}{1000000}$ th grm. of the colour.

2. A second portion of the ethereal solution is evaporated to dryness, a drop of potassium cyanide solution added to the residue, when a red coloration is obtained.

3. Another portion of residue by evaporation of the ethereal solution is mixed with potassium bisulphate, heated to redness in a glass tube, and the residue dissolved in water. A paper moistened with Griess's reagent and placed in the solution is coloured a beautiful violet.

4. A solution of Martins yellow or urine containing it, gives with cobalt chloride and a little caustic potash, a fine green pigment.

5. With stannous chloride and a trace of ammonia, Martins yellow gives a white precipitate, which becomes rose-red by subsequent treatment with ammonia.

For the recognition of Martins yellow in the stomach, intestines, &c., these are finely cut up, acidified slightly with hydrochloric acid, and digested for some hours at 40°–50° with absolute alcohol. The liquid is filtered, evaporated at a low temperature, made alkaline by caustic potash, filtered, acidified by hydrochloric acid, and shaken out with ether. The ethereal solution is then examined as above.

A dog, on being given daily doses of Martins yellow, beginning with 0.02 grm. and increasing by this amount each day, passed urine containing this colouring matter on the second day, showed poisoning symptoms on the eighth day, and died on the fifteenth day. After death, the colouring matter was found in the abdominal organs, especially the liver; examination showed hemorrhagic intestinal inflammation, and venous infiltration of brain cuticle.

Other trials on a human subject with large doses, produced yellowness of skin and unpleasant sickly feeling which soon passed away; small doses over an extended period produced no effect whatever.

The results obtained confirm Cazaneuve's observations. The small quantity that may be found in foods is shown by these experiments to be quite harmless.—W. B. H.

### *The Colour Reaction of Hydrazine Sulphate with Lignin and some Aldehydes.* E. Nickel. Chem. Zeit. 17, 1243.

THE author has compared the reaction of the most simply constituted hydrazine  $\text{H}_2\text{N}-\text{NH}_2$  with that of phenyl hydrazine, recently described by him (this Journal, 1893, 869). A cold solution of hydrazine sulphate applied to wood produces a distinct bright yellow coloration varying in intensity with different species of timber. By the action of 20 per cent. hydrochloric acid, the fully developed yellow is converted into an orange, the intensity of which gradually increases.

It having been pointed out that the colour reactions of wood with phenols and the corresponding nitrogenous compounds are owing to its aldehydic nature, the study of the reactions of hydrazine with aldehydes and ketones next suggested itself. Vanillin and cinnamic aldehyde have

both been held responsible for the colour-reactions of wood. The behaviour of hydrazine sulphate however furnishes an additional proof of the fallacy of the conclusions derived from a few colour reactions as regards the nature of a substance tested in this manner. Hydrazine sulphate solution added to an aqueous or slightly alcoholic solution of vanillin produces a strong yellow coloration, but no precipitate is formed until after the addition of hydrochloric acid. Even a continued action of the hydrochloric acid does not, as in the case of wood, change the yellow into orange. Piperonal, *p*-hydroxybenzaldehyde and salicylic aldehyde behave similarly, the last mentioned showing only a very faint yellow.—F. M.

### *The Distinction of Birch-tar from Pine-Tar.* E. Hirsch-olm. Pharm. Zeits. Russl. 1893, 32, 657.

A COMPARATIVE study of these preparations, either one or the other of which is official in the various pharmacopœias, has resulted in the following facts:—

*Birch-tar*, sp. gr. 0.920–0.945 at 20° C. When shaken with water (1:10) an almost colorless extract is obtained, possessing an acid reaction, and coloured green by the addition of ferric chloride. 5 cc. of the extract treated with 2–3 drops of aniline and 4–6 drops of hydrochloric acid, give a yellowish mixture. One volume of birch-tar mixed with 20 vols. of petroleum ether and filtered, yields a pale brown filtrate, which is not coloured green when shaken with an equal volume of copper acetate solution (1:1,000).

*Pine-tar*, sp. gr. 1.02–1.15 at 20° C. The aqueous extract is yellowish, acid in reaction, and is coloured red by ferric chloride. With aniline and hydrochloric acid an intensely red mixture is obtained which yields up its colouring matter to chloroform. The petroleum-ether extract of the tar assumes a green tint when shaken with copper acetate solution. One volume of pine-tar dissolves to a clear liquid in 9 vols. of 90 per cent. alcohol. If the solution be turbid, the presence of birch-tar, kerosene, kerosene residues, &c., is indicated.—H. T. P.

### *The Detection of Mineral Acids in the Presence of Organic Acids by Colour Reactions.* E. Nickel. Chem. Zeit. 17, 1670.

IN this test the colour reaction obtained with phloroglucinol on pine-wood shavings in the presence of free mineral acids is made use of. A shaving or splint of pine wood or bamboo wood is immersed in the acid to be tested, to which a liberal addition of phloroglucinol has been made, and finally the whole is boiled for a short time in order to completely dissolve the phloroglucinol. The colour reaction, as a rule, soon becomes perceptible, and is particularly pronounced when bamboo wood is employed, although in this case from 12 to 24 hours may elapse before the coloration reaches a maximum.—C. O. W.

### *The Detection of Mineral Acids in Vinegar by Means of Rosaniline Hydrochloride.* G. Griggi, Selmi, 1893, 3, 176.

ONE drop of a solution of rosaniline hydrochloride (25 grms. fuchsin in 100 cc. of 90 per cent. alcohol) is added to 1 cc. of vinegar contained in a shallow porcelain dish. In the case of pure vinegar, the fuchsin retains its reddish-violet colour; but in presence of small amounts of mineral acids (1 per cent.) the liquid assumes a dirty yellow tint. Addition of alkali restores the original colour of the reagent.—H. T. P.

### *Detection of Sesame Oil in Olive Oil.* F. Musset. Pharm. Central. H. N. F. 1893, 14, 701.

A SMALL piece of dry phosphorus, weighing about 0.1 grm., is dissolved, by heating in a water-bath, in 10 grms. of the oil contained in a 15 g. bottle. The cork or stopper with which the bottle has been closed is, after cooling, replaced

by a loose plug of cotton wool. By allowing the bottle to stand for some time the phosphorus becomes oxidised, the acid is formed, attracts water and run down the sides in narrow streaks.

If the olive oil is pure, milky streaks will be observed after the lapse of 24 hours, which after 48 hours will be found to have settled at the bottom in the shape of a narrow, perfectly clear ring of yellowish-brown colour. An admixture of 10 per cent. of sesame oil causes the streaks, which after 48 hours all show a distinctly yellow tint, to require almost 8 days to settle. The ring at the bottom consists in this case of two well-defined layers, a lower one of pure oil and an upper opaque and deeply colored one. With 20 per cent. of sesame oil the streaks are yellow at once and do not settle completely, while with 50 per cent. a brown ring is formed on the surface from which descend brown streaks.

Two cc. of ammonia gently added to the oil after the formation of a ring cause the latter if sesame oil be present to assume within 24 hours a more or less deep brown colour, whereas with pure oil it remains colourless.—F. M.

#### *Examination of Glue for the Manufacture of Coloured Papers.* Th. Schlossmann. *Papier Zeit.* 18, 2484—2485.

THE importance of good glue in the manufacture of coloured papers and of a simple and rapid method of estimating the value of the many qualities, which vary in price from 30 to 100 marks per kilo., will be sufficiently obvious. Absolute methods the author rejects, and recommends comparison with some approved standard quality. If a tablet of glue be covered with cold water and allowed to stand it gradually becomes softer, and a considerable increase of volume is observed. The larger the amount of water taken up in a given time, the better the quality. The moment when the tablet begins to break up must also be carefully noted. Lower qualities become slinky after 12 hours, whereas good parchment or leather glue continues to swell and to take up water for twice and thrice the space of 24 hours without breaking up. The water remains clear, containing only minute quantities of gelatin in solution, the tablet feels tough and (this is especially to be noted) there is no trace of bad smell. Inferior qualities, on the contrary, after soaking for a brief period begin to dissolve and emit an offensive odour; the water is turbid and yellowish, and the tablet breaks up on the slightest touch.

The test should be made as follows:—Two strips of the sample to be tested and of the standard are selected of as nearly as possible equal size, say 150 mm. by 50 mm., and by means of a red hot wire a hole is bored in each, about 20 mm. from the upper edge and as nearly as possible in the middle. Two graduated 1,000 c.cm. glass cylinders, 65 mm. in diameter, are filled with clean cold water exactly to the zero point, and a weighed strip is suspended in each by means of a stout brass wire with a hook at one end and a loop at the other, a glass rod being passed through the latter and resting on the top of the cylinder. The experiment should be started in the evening and the observations begun at the end of 12 hours. The strips are raised and allowed to drain back into the cylinder, and the amount of water absorbed is read off. The other points referred to above are also carefully noted, and the observations are repeated every 12 hours until the moment arrives when it is no longer possible to withdraw the strip, which is either cut through by the brass wire or entirely falls to pieces. By a comparison of the percentages of water absorbed, and of the other phenomena observed during the experiment, the relative solubility, the amount of odour emitted, &c., an accurate estimate can be formed of the value of the sample submitted to examination. A good sample, after 2 × 24 hours in summer, and 4 × 24 hours in winter, should be firm to the touch, almost insoluble in water, and above all, should emit no ill odour.—E. G. P. T.

### ORGANIC CHEMISTRY.—QUANTITATIVE.

#### *Estimation of Glue.* *Papier Zeit.* 19, 126.

THE adhesiveness of glue is in proportion to the gluten which it contains, but the chemical estimation of the latter is, in the author's opinion, of doubtful value. On the same grounds he rejects the processes based on the absorption of water (see adjoining column), and on the degree of stiffness possessed by a jelly produced by dissolving in water a certain amount of glue and allowing it to set, and recommends as the only trustworthy method that which consists in sticking pieces of wood together and measuring by means of corresponding weights the force required to pull them asunder. The wood must be thoroughly dried. Pieces 50 cm. long and 5 cm. square section are prepared, cut through the middle with a fine saw, and the cross-grained surfaces stuck together again. The glue to be tested, say 250 grms., is softened for six hours in 1½ litre of water, dissolved, and evaporated until the solution weighs 900 grms. After standing three days the test pieces, resting on each end, are weighted in the middle, 5 kilos, being added every minute until fracture ensues. Good glue should sustain a weight of at least 75 kilos.

It is a common practice with joiners to subject their solution of glue to prolonged heat in the belief that the adhesive power is thereby increased. Experiments with regard to this notion indicate that it is a delusion. In fact, the adhesive power of a glue is actually reduced after six hours boiling, from 250 to 100.—E. G. P. T.

#### *New Method of Estimating Pentosans in Vegetable Substances.* E. Hotter. *Chem. Zeit.* 17, 1743—1745.

IF a solution of furfuraldehyde is heated with hydrochloric acid and an excess of pyrogallol in a closed tube at 100° C. for a few hours, a condensation product is obtained which weighs about 1,974 times as much as the furfuraldehyde employed. On this fact the author bases his method for determining the amount of pentosans in vegetable substances.

From 5—10 grms. of the substance containing the pentosan are distilled with hydrochloric acid of sp. gr. 1.06 until the distillate no longer shows the furfuraldehyde reaction with paper impregnated with aniline acetate. The distillate is then made up to 400—500 cc. with hydrochloric acid of the above strength, and an aliquot portion of it, containing about 0.08—0.1 gm. of furfuraldehyde (usually about 20—30 cc.) taken for the estimation. An excess of pyrogallol is weighed off into a test-tube, which is then constricted near its open end before the blowpipe. After the above aliquot fraction of the solution has been introduced it is sealed off at the narrow part and heated for two hours at 100°—110° C. The precipitate which forms is collected on a weighed filter, washed, dried at 103° C., and weighed. The weight of the precipitate divided by 1,974 gives the amount of furfuraldehyde contained in the quantity of liquid employed. From this the percentage of pentoglucose in the substance is then calculated.

As certain by-products, which vitiate the results, are formed on distilling with hydrochloric acid, the author suggests that perhaps it would be advantageous to distil under diminished pressure. Operating in the way described he found 50—52 per cent. of furfuraldehyde in arabinose and xylose instead of 64 per cent.—J. S.

#### *The Estimation of Saccharine in Presence of Salicylic Acid.* Hairs. *J. de Pharm. d'Angers.*

100 cc. of the liquid to be examined (beer, wine) are acidified with hydrochloric acid, treated with a slight excess of bromine water, and violently agitated. After a short time, the almost insoluble precipitate of bromosalicylic acid is filtered off, the excess of bromine removed by a current of air, and the liquid shaken out with ether. The ethereal extract, after evaporation with addition of a few drops of sodium bicarbonate solution, leaves a residue in which saccharine may be detected by its flavour; or, after fusion with potash, by testing for salicylic acid.

—H. T. P.

*The Determination of Nitrogen in Benzene, Pyridine, and Quinoline Derivatives by Kjeldahl's Method.* M. Krüger. Ber. 27, 609—613.

THE application of Kjeldahl's process to difficultly destructible bodies, such as aromatic hydrocarbon derivatives, alkaloids, &c., has been more or less successfully attempted. Most of the suggested modifications of the method tend towards increasing the oxidative power—by the addition of metallic oxides, &c.—of the acid; nevertheless, in all cases, the bulk of the oxidation has to be done by the sulphuric acid. The author modifies the process by relegating the oxidation of the substance from the very beginning to some powerful oxidising agent, and employs for the purpose chromic acid, or preferably, potassium bichromate. The details are as follows:—0.2 to 0.8 gram. of the substance is dissolved by gently warming in 20 cc. of strong sulphuric acid in a bulb flask of 150 cc. capacity, and allowed to cool. Powdered potassium bichromate is then added in small quantities, and more or less quickly according to the violence of the reaction, the oxidation being assisted after a short time by placing the flask in a water-bath, which is gradually heated to boiling. The total amount of bichromate used should be in excess of that required by theory for the oxidation of the substance (generally 15—20 parts to 1 part of substance). Finally, when the evolution of CO<sub>2</sub> has ceased, the flask is heated for 10 minutes over a small naked flame, allowed to cool, and the distillation of the contents proceeded with as usual. The numerous test

analyses given are excellent. Attempts to apply the method to nitro-, nitroso-, azo-, and similar bodies proved unsatisfactory.—H. T. P.

*The Analysis of India-Rubber Goods.* D. Hilde. Chem. Zeit. 17, 1631—1635 and 1670—1671.

IN a former paper (this Journal, 1893, 463) the author proposed to estimate free oils in india rubber articles, by means of extraction of the finely-subdivided samples with ether-alcohol (1:3). If the extraction is effected with the solvent warm, the process is very tedious, owing to some of the other constituents of the india-rubber articles also slowly dissolving, in consequence of which even a four times repeated extraction is not sufficient to completely exhaust the samples. For the extraction of the free oil alone, however, treatment with the cold solvent was found to succeed in one operation. About 1 gram. of the finely-divided substance is placed on a filter in a funnel, and extra ted with 50 cc. of ether alcohol. The filtrate was collected in a weighed Erlenmeyer flask, the solvent distilled off, the flask dried in an air bath and subsequently weighed again. The weight of oil so obtained requires, however, a correction, owing to the solvent action of the ether alcohol upon the caoutchouc itself, of which it dissolves on an average 5 per cent., the observed maximum being 7 per cent. The working of the method will be seen from the following results:—

Nature of India-Rubber Article.	Nature of the Added Oil.	Quantity of Oil Added.	Per Cent. of Oil found.		Total Extract.	Ether-Alcohol Employed.

White tubing reduced to coarse granular fragments.

In a former paper (this Journal, 1893, *loc. cit.*) the author showed that the india rubber substitutes prepared from fatty oils by means of sulphur chloride, yield only traces of sulphur to ether-alcohol, so that the above process offers a means for the separation from india-rubber of the fatty oils in the presence of such substitutes. Should any rubber sample also contain mineral oils, resin oil, &c., which are also soluble in ether-alcohol, the further quantitative examination of the extract by well-known methods becomes necessary.—C. O. W.

*The Estimation of Indigotine in Indigo.* C. Donath and R. Strasser. *Zeits. f. ang. Chem.* 1894, 49.

1 GRM. of the finely ground indigo is weighed out in a weighing flask, and mixed therein with four times its volume of moderately fine, dry pumice stone sand. This mixture is then placed in a spacious Soxhlet extractor, on the bottom of which is firmly secured a layer of asbestos fibre, reaching above the opening of the lateral siphon (see Fig.), and covered with a thin layer of pumice stone sand. The weighing flask, after being emptied into the extractor, is also rinsed with pumice stone sand. The indigo is then extracted with water and hydrochloric acid, a small quantity of the latter being added through the condenser as soon as a sufficient quantity of water has accumulated in the extractor. The extraction of the glutinous matters is complete after 15 minutes' boiling, and the indigo is then washed with hot water, which is poured direct into the extractor. The extractor is then adjusted to the neck of a flask half filled with a mixture of four parts of alcohol and one part of ether, and with this mixture the indigo is extracted until the brownish-red colour of the indigo-red has altogether disappeared, the liquid running from the extractor being perfectly colourless, or at most only exhibiting a faint blue coloration. The extractor, with contents, is now completely dried at from 100° to 110° C. The delivery end of the siphon of the extractor is then closed with an asbestos plug, the contents of the extractor are completely covered with concentrated sulphuric acid, and the extractor, by means of copper wires, is now suspended in an air-bath (see Fig.). This air-bath consists of the copper cylinder A closed at the bottom and placed on a tripod. After heating the apparatus for from 1½ to 2 hours to 80° C. the sulphonation of the indigo may be relied upon as completed. The extractor is then left to cool, subsequently the plug removed from the siphon and distilled water poured into the extractor. The indigo-sulphonic acid formed is thus siphoned off and collected in a litre flask, the last traces of

dye may be removed from the asbestos by washing with boiling water. The contents of the litre flask are allowed

to cool, and the whole is then made up to 1,000 cc. 100 cc. of this solution are diluted with 400 cc. of water and titrated with a solution of permanganate, 1 cc. of which corresponds to 0.0099139 gram. of indigotine. Four estimations of a Bengal indigo showed the percentage of indigotine in four experiments to be 54.53, 54.13, 54.62, and 54.73 per cent. respectively.—C. O. W.

*Analysis of Tanning Materials.* A. Folsing. *Chem. Zeit.* 17, 1770—1771.

THE gravimetric method of estimating the tannin in a tannin is open to the objection that a number of other substances, such as metallic salts, phenols, alcohols, picric acid, &c., are precipitated by hide, and therefore included in the difference between the total solids and the solids not tannin.

Schreier's method of valuing a tanning material, not applicable to extracts, is devised for the examination of raw materials with simple appliances. It consists in introducing 50—100 grms. of the ground material into a flask, together with 1 litre of water at 15°; the flask is corked and shaken intermittently during 24 hours. At the end of this time the liquor is filtered through paper, and its specific gravity is taken by means of a special hydrometer; comparison with published tables shows the percentage of tannin which would be contained in a liquor from the same class of material and of the same specific gravity.

The colour and turbidity of extracts may be compared by measuring 10 cc. of each into a litre cylinder, adding water to the mark, shaking, and allowing the cylinders to stand before a window for half an hour, when a comparison may be made. In the case of a solid extract 5 grms. should be weighed out and dissolved in 10 cc. of water in a dish on the water-bath; the sample may then be treated as described above. Equality of temperature is important in making the comparison.

The author's colorimetric method consists in placing 0.5 gram. of the sample and of a sample of the same species of bark of known tannin-content, in each of two "colour glasses." Equality of water content is necessary, so that each sample must be dried at 110° before being weighed. Half a litre of water is added to each glass, and then a strip of textile material, which is subsequently dyed with madder on the water-bath. The dried strips are then compared. The quality of the shade will indicate which specimen is the poorer in tannin. Extracts must be prepared for this test by weighing 2 grms. into a litre flask, making the solution up to the mark, and transferring 100 cc. to the "colour glass," containing half a litre of water.

The introduction of hydrogen dioxide as a bleaching agent for leather is noteworthy. Foelsing's electrical tanning process differs from others in that the hides are kept at rest and the liquor in motion; it is alleged to have proved of service in tanning heavy leather.—A. G. B.

*The Oxidation of the Fatty Oils.* W. Fabrian. *Chem. Zeit.* 17, 1453.

See under XII., pages 404 and 405.

*Analysis of Mixtures of Sperm Oil and Mineral Oil.* C. A. Lobey de Bruyn. *Chem. Zeit.* 17, 1453.

PURE sperm oil contains at least 25 per cent. of the higher primary alcohols, which are insoluble in water, and can be separated from the solution of the saponified oil in alcohol by means of petroleum ether (this Journal, 1892, 134—145). In applying to such an oil Holde's test for the detection of mineral oil in sperm oil (boiling a few drops of the oil with the solution of a small piece of caustic potash in a few cc. of alcohol) and diluting the soap solution so obtained with water, the higher alcohols remain for a considerable length of time dissolved in the soap solution, so that this test can be used for the detection of mineral oil in sperm oil.

Sperm oil may be adulterated with seed oil, such mixtures possessing the same specific gravity as pure sperm oil. Mixtures of this kind are analysed according to Allen and Thomson's method, by heating 5 grms. of the oil with a solution of 2 grms. of caustic soda in 25 cc. of alcohol, but it is advisable to boil for some hours previous to evaporation. The residue obtained on evaporation is dissolved in water, and the unsaponifiable matter extracted by twice shaking the solution with petroleum ether. The latter is distilled from a weighed flask. For the separation of the mineral oil and the higher alcohols in the residue obtained after distillation, it is boiled for half an hour with twice its volume of acetic anhydride. On cooling, any mineral oil present separates out completely, the higher alcohols remaining in solution. The two layers are separated, the mineral oil is distilled off, washed with dilute alkali, dissolved in petroleum ether, and after drying the latter with calcium chloride it is distilled off. Pure mineral oil remains behind. The acetic anhydride separated as above from the mineral oil, contains the higher alcohol in the form of esters. These may be obtained by diluting the acetic anhydrides with water, when the esters of the higher alcohols separate out, forming an oily layer upon the surface of the water. Amagat and Jean's refractometer also appears to prove very useful in testing the purity of sperm oils. — C. O. W.

*Note on some Modifications of the Reichert-Meissl Method of detecting Margarine in Butter, and a New Method for the Determination of the Reichert-Meissl Number.* C. Bunte. (Chem. Zeit. 13, 201-206.)

THE author has investigated Kreis's method of saponifying butter-fat by means of sulphuric acid, in order to determine the influence of various factors, such as the concentration of the acid employed, temperature, &c., on the resulting "Reichert-Meissl" numbers. The figures obtained are given in a series of tables, as also, for the sake of comparison, the Reichert-Meissl values obtained in the ordinary way. From these it appears that:—

1. Small variations in the initial temperature of the butter-fat cause considerable differences in the R.M. value.  
2. When Kreis's directions are strictly adhered to, the figures obtained fall considerably below the truth, in spite of the sulphurous acid which is *always* formed and which of course raises the results.

3. In Kreis's method, therefore, saponification is incomplete, the degree of completeness depending on the concentration of the acid and the temperature of the butter.

4. Taking also into account the difficulty of preparing strong sulphuric acid of a particular specific gravity, Kreis's method must be entirely condemned.

The author finds, however, that by slightly modifying the process, reliable figures may be obtained which compare well with those yielded by the Reichert-Meissl method. The details are as follows:—5 grms. of the butter-fat to be examined, contained in an Erlenmeyer flask (1,000 cc. capacity) are heated to 100° C. in a drying chamber. 10 cc. of sulphuric acid (1.8355 sp. gr.) are then added, the flask shaken until the butter is dissolved, and placed for 10 minutes on a water bath maintained at 30°–32° C. 150 cc. of water are then added with constant agitation, the liquid titrated with strong permanganate solution until the red colour remains permanent for a few moments, and finally distilled in the usual way. It is essential that the above directions be carried out to the letter. The sulphuric acid should be exactly of the strength indicated (to the third place of decimals). (This Journal, 1893, 872 and 952.)—H. T. P.

*The Determination of the Reducing Action of Organic Substances contained in Water upon Permanganate of Potassium.* A. Zega. Chem. Zeit. 18, 2.

THE author has found the methods of Kubel and Schulze defective in the case of volatile organic substances, and proposes instead the following:—50 cc. of the water to be tested are placed in a globular flask with a capacity of about 100 cc. 5 cc. of the usual solution of permanganate are added and 5 cc. of dilute sulphuric acid (1 vol. acid to

2 vols. water). The mixture is placed on a boiling water bath for 20 minutes and the remaining permanganate titrated as usual with oxalic acid.—J. H. C.

*Determination of Oil of Turpentine in Alcohol.* J. Perl. Chem. Zeit. 17, 1851.

FOR certain purposes alcohol is denatured with oil of turpentine. The quantity of oil present in a given sample may be determined by distilling a known quantity over quickly, and determining how much water must be added to the distillate to produce permanent turbidity. Alcohol actually containing 0.5 per cent. was thus found to contain 0.11 when valued by comparison with undistilled mixtures of alcohol and oil of turpentine; when the distillate was collected in four nearly equal fractions, the first indicated 0.5, the second and third 0.14, and the last 0.1 per cent., average = 0.44.—C. R. A. W.

## ANALYTICAL AND SCIENTIFIC NOTES.

### *International Standards for the Analysis of Iron and Steel.*

At the World's Congress of Chemists in Chicago, a sub-committee of the original committee on international standards for the analysis of iron and steel, was appointed to consider the subject of standard methods.

This sub-committee consists of Dr. C. B. Dudley, chairman, Messrs. A. A. Blair, W. P. Barba, P. W. Shimer, and T. M. Brown. It has recently held a meeting and has decided to recommend standard methods in iron and steel analysis, to be used as the basis of commercial transactions. The sub-committee fully appreciates the fact that these methods, to have the highest value, should be in facility and in time of execution such that they will readily recommend themselves for daily use in iron and steel works.

To further this end, the sub-committee wishes to have the co-operation of the iron and steel chemists of the country, and to ask them for a brief outline of the processes or methods they use and prefer for the determination of different elements in iron and steel, and for such other information and suggestions as they think will aid it in the work before it. The sub-committee recognises the fact that it will add immensely to its efficiency and value if the iron and steel analysts of the country will take a personal interest in it, and aid it by their counsel and active influence.

They are therefore requested to send to the chairman of the sub-committee, as soon as convenient, such an outline as they may deem sufficient to fully describe their practice. It is suggested that they follow the general plan here indicated, by answering the following questions, which may be referred to by number to save unnecessary trouble:—

1. What general method do you use for the determination of phosphorus in iron and steel?

2. What special precautions do you consider necessary to make this method reliable?

3. What precautions do you take to prevent the interference of arsenic?

4. What factors do you use in your calculations?

5. What variations do you introduce in the case of iron ores or slags?

6. Do you use the same method in pig iron and steel, and do you consider the results equally reliable?

7. Do you ever examine the residues insoluble in acid, in pig irons, or iron ores, and do you ever find phosphorus in them?

8. Are all your determinations made by the same method, or do you check your work by reference to another method, and if so, what method do you use for this purpose?

9. How many determinations do you make a day in your laboratory under ordinary circumstances?

10. What do you consider the greatest length of time necessary to obtain a result, permissible in your work?

The sub-committee begs that chemists will send at the earliest possible moment as full replies to all or any of the above questions as they conveniently can, and assures them

that in making use of any details that may be original, they shall have full credit. They will likewise be furnished with copies of the various reports. Replies should be sent to Dr. Chas. B. Dudley, Chairman, Sub-committee, Altoona, Pa.

*Colloidal Lead Chloride.* A. van de Velle. Chem. Zeit. 17, 1908.

On mixing together two solutions, one containing 379 grms. (1 molecule) of sugar of lead, the other 117 grms. (2 molecules) of sodium chloride per litre, a slimy precipitate forms consisting of a mixture of amorphous lead chloride and crystals of the same substance. Excess of one or other salt does not alter the result but the weaker the solutions the more the crystalline predominates; on filtering, the liquid passes through turbid, whilst what remains on the filter becomes crystallised on washing with water. Potassium, ammonium, calcium, or bromium chloride may be used instead of sodium chloride; hydrochloric acid, however, forms only a crystalline precipitate. Basic lead acetate or lead propionate, formate, or lactate may be used instead of sugar of lead, but lead nitrate, chlorate, or perchlorate only yield fine crystals.—C. R. A. W.

*Electrical Phenomenon observed in the Preparation of Salipyrine.* D. Schrijnen. Pharm. C.-H., N.F., 1893, 14, 727.

The crystalline product obtained by allowing the oily liquid to cool, which results from the treatment on the water bath of antipyrine with salicylic acid and water and subsequent evaporation of the latter, emits when crushed in a mortar a fine bluish-white light, the peculiar crackle of electric sparks being at the same time noticeable. On grinding the substance in the dark these sparks may be seen in profusion. The electricity is supposed to be generated by the friction of the crystal surfaces against each other.—F. M.

*Measurement of Radiation of Light by means of the Radiometer.* N. Techn. Journ. Prakt. Chem. 47 (1893), 568—583.

With the object of finding whether Crookes's radiometer could be employed in measurements of diaphaneity (diaphanität) towards radiant energy, the author first investigated a method of determining accurately the rate of rotation of the vanes of the radiometer.

The radiometer was enclosed in a metal case blackened on the inside and open in the direction of the radiation. The case was also provided with a side-tube (also blackened on the inside), through which the observer could examine the vanes. When a rotating vane came into a certain position with reference to the source of light and the observer's eye, a flash of light was seen. With the aid of a chronoscope the instant at which this occurred was noted. A suitable number of vane-transits were observed and counted, and the time which had elapsed was again determined with the aid of the chronoscope. The method is susceptible of considerable accuracy, and was first employed in testing the ratio between the number of vane-transits in a given time when the source of light was (a) at a distance of 20 cm., (b) at a distance of 40 cm., from the radiometer. In three successive experiments the ratio of (a) to (b) was found to be 3.95, 3.99, and 4.00.

This is exceedingly near the theoretical value of 4 : 1, and shows that the rate of rotation of the radiometer-vanes is a correct measure of the intensity of radiation.

The author appears subsequently to have become aware that Crookes had already shown this, although in a somewhat different manner.

In endeavouring to measure the diaphaneity of bodies (glass plates, liquids in flat troughs, &c.), the author had either to rely upon the absolute constancy of some source of light, or else to devise a method which should be quite independent of this. The method adopted consisted in using two independent radiometers, which were first placed at such distances from the source that they rotated at the

same speed. The plate or solution to be examined was then introduced in front of one of them, and by readjusting the distances the rates of rotation could again be equalised. Some of the results obtained are given below, the diaphaneity of water being in all cases taken as 100 :—

(1.) Saturated aqueous solutions exhibit only slight differences in diaphaneity.

Water.....	100.00
Sodium chloride.....	103.75
Oxalic acid.....	98.79
Citric acid.....	101.37
Boric acid.....	99.69
Borax.....	99.14
Sugar.....	101.29
Alum.....	99.06
Tartaric acid.....	99.89
Ammonia.....	99.62

(2.) The diaphaneity of compounds of the fatty series increases with increasing molecular weight.

(3.) In the case of aromatic compounds the converse is true—

Benzene.....	128.62
Toluene.....	126.32
Xylene.....	124.95

(4.) Some isomeric compounds differ greatly in diaphaneity, e.g., acetic acid and methyl formate, ethyl acetate and butyric acid, methyl butyrate and valeric acid; whereas others only differ very slightly, e.g., propyl- and isopropyl-alcohol, butyl- and isobutyl-alcohol.

(5.) The diaphaneity of carbon bisulphide (141.70) exceeds that of glass (140.77); and it is remarkable that carbon tetrachloride (145.77) is more diaphanous than air (142.26).—D. E. J.

*Decomposition of Liquids by Contact with Powdered Silica.* G. Gore. Phil. Soc. of Birmingham, 1893, 9 [1], 1—24.

A SOLUTION of an acid, alkali, or salt, having no chemical action on pure precipitated silica, was well shaken up in a bottle with 50 grains of the silica, and after 16 hours' standing it was found that the film of liquid adhering to the powder contained a higher percentage of the dissolved substance (acid, alkali, or salt) than the supernatant solution itself in bulk. The amount of solid thus abstracted from the solution varies with the kind of powder employed, its degree of fineness, the character of the dissolved substance, the ratio of the powder to dissolved substance, the nature of the solvent, the proportion of solvent to powder, the degree of dilution of the solution, and to a certain extent to the temperature. The union ensues quickly and prolongation of immersion has but little influence. Finely precipitated silica possesses the property in the highest degree, and alkaline substances are most affected. With very dilute alkaline solutions more than 80 per cent. of the dissolved substance was abstracted by the silica. The results throw some light undoubtedly upon :—

(a.) The purification of water by sand filtration.

(b.) The retention of the alkaline constituents of soils, in a greater degree by the silica than by the alumina.

(c.) The great losses incurred by the gold extractor (MacArthur, Forrest process) through the action of the silica of the pulverised quartz upon the weak potassium cyanide solutions employed for the extraction of gold and silver. It is a case of simple adhesion of the cyanide to the silica (see also p. 339).—W. S.

## New Books.

**ODOROGRAPHIA.** A Natural History of Raw Materials and Drugs used in the Perfume Industry, including the Aromatics used in Flavouring; intended for the Use of Growers, Manufacturers and Consumers. By J. CH. SAWYER, F.L.S. Second Series. London: Gurney and Jackson, 1, Paternoster Row (Successors to Mr. Van Voorst). Brighton: W. J. Smith, 43, North Street. 1894. 15s.

THIS forms the second volume of the handbook bearing the above title, the notice of the first volume having appeared in this Journal, 1893, page 71. It is of similar size and appearance, and contains 74 illustrations of various plants, &c., bearing essences, oils, &c.

The number of pages of subject-matter in this volume is 523, the final two pages being occupied by a table representing the "Solvent Power of Essential Oils" and a Table of Weights and Measures, &c. The work commences with a Preface, a Table of General Contents, a List of Illustrations, and another of Principal Works referred to, with Abbreviations.

The whole work is divided into five sections. SECTION I. commences with Nutmegs and Mace, Sassafras, Laurus Penzance, Pimento, Myrtle, and ends with Mint, Chamomile, Eucalyptus, and Odorous Waxes. It occupies pages 1 to 346.

SECTION II. treats of Ferment Oils, Ferments, Organic Ethers, Bouquet of Wines, Brandies, &c. Theory of Compound Odours, Oil Secretions, &c. Pages 347—376.

SECTION III. Emphysematic Oils and Aromatic Products of Destructive Distillation, including Russia Leather, Casearilla, Caffene, Furfural, &c. Pages 377—394.

SECTION IV. Addenda to Volume I. Vanillin, Musk Substitutes, Rosemary, Cloves, Mignonette, Rose, Lavender, Geranium, Bergamot, Violet, and Orris, &c. Pages 395—457.

SECTION V. Descriptive of Plants yielding purely Floral Perfumes. Pages 459—520.

The work ends with an Alphabetical Index.

**A HANDBOOK OF GOLD MILLING.** By HENRY LOUIS, Assoc. Roy. School of Mines, &c. London and New York: Macmillan and Co. 1894. 10s.

8vo. volume bound in cloth, containing frontispiece representing a Stamp Mill in the sixteenth Century, Preface, Table of Contents, Subject-matter, covering 477 pages, an Appendix of 16 pages, and an Alphabetical Index. The text is illustrated with upwards of 118 well-executed wood-engravings. The subject is subdivided for treatment in the pages of this work, as follows:—I. Mode of Occurrence. II. Physical and Chemical Properties of Gold. III. Physical and Chemical Properties of Mercury. IV. Alloys and Amalgams of Gold. V. Primitive Methods. VI. General Arrangements. VII. The Stamp, Tappet, Stem, Head, Shoe, Cam Shaft, &c. VIII. Frames, Guides, Hoisting Gear, Water Supply, Ore Feeders, &c. IX. Other Crushing Machinery. Huntington Mill. X. Amalgamation, &c. XI. Principles of Concentration. XII. Treatment of Concentrates, Amalgamation, Chlorination, Cyanidation, &c. XIII. Cleaning-up, Treatment of Amalgam, &c. XIV. Modes of Treatment, Cost of Milling, Returns. XV. Sampling and Assaying of Ore, Tailings, Concentrates, and Bullion.

**THE GAS ENGINEER'S LABORATORY HANDBOOK.** By JOHN HORNBY, F.I.C. London: E. and F. N. Spon, 125, Strand. New York: Spon and Chamberlain, 12, Cortlandt Street. 1894. 6s.

THIS little work is dedicated by the author to his chief, Mr. John Methven, of the Beckton Works. Part I. treats of various preliminary operations in general quantitative work. II. Describes the methods of estimating gravimetrically, certain pure substances, and typical of the more

ordinary analyses conducted in gasworks. III. General account of operations connected with volumetric analysis, followed by some simple volumetric processes applicable to gas-testing. IV. Describes the more complex determinations required in gasworks, some gravimetric, some volumetric. Methods of Analysis of Coal, Fresh and Spent Purifying Material, Ammoniacal Liquor, Firebricks and Clay, Tar, Crude Gas and Purified Gas, &c., are described. V. Technical Gas Analysis, &c. The work is illustrated with 63 engravings, and numerous tables are given. An alphabetical index is supplied. The book contains 296 pages of subject-matter inclusive of appendix containing the tabular matter.

**TABELLÄRISCHE ÜBERSICHT ÜBER DIE KUNSTLICHEN ORGANISCHEN FARBSTOFFE UND IHRE ANWENDUNG IN FÄRBEREI UND ZEIGERIECK.** Von Dr. ADOLF LEHNE. Herausgeber der Farber-Zeitung. Vierte Lieferung. Berlin: Verlag von Julius Springer. 1894. London: H. Grevel and Co., 33, King Street, Covent Garden.

THIS beautifully illustrated work has now reached the issue of Part IV., which contains dyed and printed samples illustrating colours No. 180—219, commencing with Benzo-brown G and ending with Pyronine G. (This Journal, 1893, 633.)

**TEINTURE ET IMPRESSION.** Par M. PRUD'HOMME, Ancien Élève de l'École Polytechnique. Paris: Gauthier, Villars et Fils, Quai des Grands-Augustins 55. G. Masson, Éditeur, Libraire de l'Académie de Médecine, Boulevard St. Germain 120. London: H. Grevel and Co., King Street, Covent Garden. 1894. 3 francs.

SMALL 8vo volume, in cardboard cover, and containing 187 pages of subject-matter, a bibliographic list, and a table of contents.

In the text the following subjects are treated of:—I. Fixation of Colouring Matters. II. Mordants. III. Fixation of Mordants. IV. Garancine and its Artificial Substitutes. V. Indigo. VI. Aniline Black. VII. Albumin Colours. VIII. Aniline Colours. IX. Azo Colours. X. Reserves and Discharges (*enlevages*). XI. Alterations of the Fibres of Tissues. XII. Fastness of Colour.

**GRUNDRISS DER PHARMACOGNOSIE.** Von F. A. FLÜCKIGER. Zweite, mit Berücksichtigung technisch wichtiger Pflanzen bearbeitete Auflage. Berlin: R. Gaertner's Verlagshandlung. Hermann Heyfelder, Schönebergerstr. 26, S.W. London: H. Grevel and Co., King Street, Covent Garden. 7s. ; or bound, 8s.

OCTAVO volume, bound strongly in cloth, and containing Preface, Table of Contents, subject-matter covering 309 pages, and an Alphabetical Index. The principal division of the subject-matter is into two branches. I. Drugs obtained from the Vegetable Kingdom; and II. Those derived from the Animal Kingdom. The first receive a thoroughly scientific and complete classification in the table of contents, according to the natural orders to which they belong. A second table of contents then follows, in which the matters are classified according to their chemical and physical properties, as is usually done. *First Class.* Vegetable Matters without Organic Structure. I. Gums and Gummy Matters. II. Sweet Substances. III. Resin mixed with Gum. IV. Resin with Etheral Oils and Gums. V. Resin with Considerable Amounts of Etheral Oils. VI. Resins. VII. Balsams. VIII. Etheral Oils. IX. Fats and Waxes. X. Milk Juices and their Constituents. XI. Extracts and Colours. *Second Class.* Organic Matters of the Vegetable Kingdom. XII. Powders. XIII. Galls. XIV. Non-powder Vegetable Organs. Animal Matters and Products. A. Entirely Animal. B. Parts of Animals. C. Products from Animals.

## Trade Report.

### TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

#### VICTORIA.

##### Tariff Changes.

By an Act assented to on the 13th October, the specific duties on sugar of all kinds are doubled. It is provided that, dating from the 14th September 1893, a rebate of 3s. per hundredweight was to be allowed to manufacturers on all sugar used in the manufacture of ale, beer, cordials, syrups, jam, jellies, and preserves, and on all sugar and glucose used in the manufacture of confectionery, such rebate to be allowed only to licensed or registered manufacturers under regulations to be approved by the Governor in Council, and in respect of sugar and glucose upon which the increased duty under this Act has been paid. The following are the new duties leviable upon sugar:—

Sugar, not being the produce of sugar-cane, 12s. per cwt.  
 Sugar, the produce of sugar-cane, 6s. per cwt.  
 Sugar, the produce of sugar-cane, and refined in Victoria in a bonded warehouse, 3s. per cwt.  
 Glucose, 6s. per cwt.  
 Molasses, refined, 6s. per cwt.  
 Molasses, refined, in bond, 4s. per cwt.  
 Molasses, unrefined, 2s. per cwt.  
 Candy, 4d. per lb.

#### THE ALCOHOLIC STRENGTH OF IMPORTED SPIRITS.

The West India Committee of Billiter House, London, E.C., having requested that a statement should be inserted in the *Board of Trade Journal* of the method adopted in the Customs department of ascertaining the true alcoholic strength of spirits to which sweetening, colouring, or other matter interfering with the free action of the hydrometer has been added, the Board of Customs state that they have found that the correct strength of spirit, such as rum, in which colouring or sweetening matter is present, cannot be ascertained by Sykes's hydrometer without first distilling the spirit, and that, under the law as it now stands, the Customs resort to distillation in the first instance for the purpose of ascertaining the true alcoholic strength of such spirits by Sykes's hydrometer.

#### THE NEW SPIRIT DUTIES.

The increased spirit duties proposed by the Chancellor of the Exchequer in his Budget Bill came in force on April 1<sup>st</sup>. Should the Bill fail to pass and the duty remain unchanged, any excess paid will be returned by the Government. The following resolution was adopted by the House of Commons on Monday night, and went into immediate effect:—That, in addition to the duties of Customs now payable on spirits, there shall be charged and paid the duties following (that is to say):—

	£	s.	d.
For every gallon computed at proof of spirits of any description except perfumed spirits.....	0	0	6
For every gallon of perfumed spirits.....	0	0	10
For every gallon of liquors, cordials, mixtures, and other preparations entered in such a manner as to indicate that the strength is not to be tested.....	0	0	8

And the duties of Customs on the articles hereinafter mentioned, being articles of which spirits are a part or ingredient, shall be proportionally increased, and shall be as follows:—

	The lb.	£	s.	d.
Chloral hydrate.....	The lb.	0	1	4
Chloroform.....	"	0	3	3
Collodion.....	The gallon	1	6	3
Ether acetic.....	The lb.	0	1	11
Ether butyric.....	The gallon	0	16	5
Ether sulphuric.....	"	1	7	5
Ethyl iodide of.....	"	0	14	3

The excise duty on spirits distilled in the United Kingdom is increased by a separate resolution.

The advance on chloral hydrate and acetic ether amounts to 1d. per lb.: on chloroform, to 2d. per lb.; on iodide of ethyl, to 8d. per gallon; on butyric ether, to 9d. per gallon; and on sulphuric ether and collodion, to 1s. 3d. per gallon. —*Chemist and Druggist.*

### EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

#### BALATA PRODUCTION IN SURINAM.

In his report on the trade and commerce of Surinam during 1893, Mr. E. W. Smith-Delaconr, Her Majesty's Consul at Paramaribo, gives the following particulars of the production of balata in Surinam:—

One of the most valuable forest products of Surinam, and which has been considerably exported, is the caoutchouc-like substance known as balata. Balata gum holds the first place among the substitutes for gutta-percha. It is obtained from the minussops balata. The balata gum combines in some degree the elasticity of caoutchouc with the ductility of gutta-percha, freely softening and becoming plastic, and being easily moulded like gutta-percha. The tree which produces this is widely distributed over the colony, even in parts so far in the interior as to have been hardly visited as yet; and the industry, now that experience has taught how it can be carried on without the wasteful extermination of the tree, should have a positive future value. Better means of access and of working are required before the expenses of production form the proper proportion of the value produced.

Balata is principally exported to the United States of America, small consignments also reaching Holland and Great Britain.

The total production in 1893 was estimated at 113,018 lb., valued at 6,347*l.*, as compared with 265,976 lb., valued at 15,070*l.* in 1892, showing a decrease in quantity of 152,958*l.*, and in value of 8,723*l.*—(*No.* 1329, *Foreign Office Annual Series.*)

#### PRODUCTION OF BANANA-MEAL IN SURINAM.

Mr. E. W. S. Delaconr, Her Majesty's Consul at Paramaribo, in a report to the Foreign Office, dated the 15th February, states that a company has lately been established at plantation "Susannasdaal" in the colony of Dutch Guiana, for the purpose of reducing into meal the large quantities of bananas and plantains grown on cocoa estates in the district. The banana trees are originally planted as shade for the young cocoa trees, and to such an extent that much of the fruit is wasted. Machinery and plant have been imported to the value of about 2,000*l.*, and a small amount of meal has already been produced and sent to Holland.

The company anticipate that a large quantity of banana meal for bread-making will be sold to the estates on which British Indian immigrants are engaged.

Mr. Delaconr encloses the following analysis of the Surinam banana:—

Analysis of banana-meal:—	
Moisture.....	11.44
Ether extract.....	0.30
Alcohol extract (80 per cent.).....	5.94
(of which, reducing sugar 1.18 per cent.)	
(of which, saccharose 0.08 per cent.)	
Cold water extract.....	5.33
Fibre.....	1.11
Ash.....	3.04
Starch.....	59.35
Albuminoids.....	5.25
Digestible fibre and other undeterminable carbohydrates	8.15
Total.....	100.00

From this it will be seen that the food value of the meal is minute, and should be compared rather to the potato than to a cereal.

In the face of this analysis, it is difficult to believe, says Mr. Delacour, that the banana-meal enterprise will prove remunerative, especially when it is remembered that so soon as the cocoa trees are sufficiently strong to bear the sun, the cultivation of the banana tree as shade will be no longer necessary, and the supply will consequently become limited. — *Board of Trade Journal*.

#### THE UNITED STATES DWYWOOD INDUSTRY.

*U.S. Consular Reports. March 1894, 438—450.*

The report includes statements with regard to the dyewood industries of Haiti, Mexico, Colombia, and Jamaica, compiled by the United States Consular officers in those places.

##### *Haiti.*

The port of Cape Haitien has for several years exported more logwood than any other port in the world. A notable decrease in the export of logwood has taken place during the last few years. A maximum was reached in 1881, when 157,322,650 pounds were exported, while in 1892 the amount was only 39,766,320 pounds. The logwood-producing forests are being rapidly destroyed, and, should the present rate of destruction continue, Haiti will cease to export logwood in 15 years, although much remains at present in districts remote from public roads.

##### *Mexico.*

Mexico produces many dyewoods, the best known being logwood, brazil wood, and fustic. These grow in profusion along the coast, and more sparingly in the interior. The principal markets are England, United States, Germany, France, Spain, and Russia. The export of 'Palo Moral' or fustic amounts to 9,000,000 kilos, a year. Notwithstanding the reckless way in which the trees are cut down, the supply is said to be almost inexhaustible. The Government has placed an export duty on logwood of 1.50 dol., and on fustic of 75 cents per 1,000 kilos.

In the district of La Paz are found two little-investigated dyewoods known as "lombay" and "torote," which yield red colonies.

##### *Colombia.*

The dyewood industry in Panama is of recent growth. Fustic is the only dyewood exported, and in 1893 the solitary shipper of this wood sent 560,000 lb. to Liverpool and Havre. From Colon, about 4,000 to 5,000 tons are annually exported.

##### *Jamaica.*

*Logwood* grows in the low-lying parts of the island. Considerable care is bestowed on its cultivation, and the demand for it is steady. The amount exported in 1893 (an average year) was 92,621 tons, of which 37,444 tons went to the United Kingdom.

*Fustic* is obtained in the mountainous districts. The total export during 1893 was 6,461 tons, of which 3,016 tons went to the United Kingdom. The demand at present is very slight. There is no probability of the supply being exhausted.

*Green-Heart Ebony.*—There is very little demand for this wood, only 146 tons being exported in 1893.

There is in process or erection at Spanish Town, in this island, a plant for the extraction of dye from these woods; but it is not believed that, even if successfully operated, it will diminish the exportation of the dyewoods.—R. B. B.

#### GENERAL TRADE NOTES.

##### THE MINERAL INDUSTRY OF GREECE.

The accompanying table of production shows clearly the bad effects which the fall in prices of the chief metals has had upon the mineral industry of Greece. The English coal strike also contributed to this by increasing the freight charges. The chief sufferers from low prices were the zinc producers and the lead works of Laurium, while the increase in freight affected the iron ore mines of Laurium and of Seriphos. The high exchange of gold, which stood at 160 per cent. (one franc, gold = 1.60 drachme), somewhat lessened the bad effect of low prices.

One of the chief smelting works, Laurium, treated exclusively the old slags and dump-heaps. The slags are nearly all worked out, and of the dump-heaps only the poorer portions remain, viz., those containing 3—4 per cent. lead, and 70—100 grms. silver per ton. Concentrating works capable of treating 1,000 tons of raw material per day were completed during 1893. There were about 6,700 tons produced from these old dumps during the year, the rest of the lead or a little more than half being obtained from new workings, from which only the purest galena was extracted. The average silver contents of the lead was about 2,000 grms. per ton. Since their erection to the end of 1893, the Laurium works have smelted 283,800 metric tons of lead, to the value of 31,860,000 dol.

The Laurium mines have also produced considerable quantities of zinc ore. Since 1875 to the end of 1893 there have been exported from these mines 555,000 metric tons of calcined calamine, of the value of 12,265,000 dol. There has been a gradual decrease in the production of zinc ores in the last few years, due to the exhaustion of old workings, but there exist several deposits which, only require to be properly developed to yield large quantities.

Since 1881, manganiferous iron ore, containing 33—40 per cent. iron, and 12—18 manganese, which (if it contained 1 to 6 per cent. lead) had only been used as flux, has been exported. It is estimated that altogether about 200,000 tons have been consumed as flux, while to the end of 1893, 1,065,880 tons of the value of 2,679,500 dol. have been exported.

*Iron Ores of Seriphos.*—The iron mines of Seriphos are very ancient, the island being used by the Romans as a colony for convicts, who were made to work the mines. Exploitation was commenced in 1870, but there were only 42,000 tons produced to the year 1880. Since then a French company has operated the mines, and has exported the following quantities in tons of 2,000 lb. :—

Year.	Total Exports.	Exports to United States.
1881	5,159	.. ..
1882	6,250	.. ..
1883	28,109	4,800
1884	21,645	13,185
1885	7,354	3,900
1886	32,640	24,300
1887	51,215	19,380
1888	18,170	6,950
1889	37,759	18,775
1890	89,470	36,120
1891	75,750	19,580
1892	112,445	41,440
1893	67,070	.. ..
Total .....	554,135	217,170

The hematite ores contain: 46—48 per cent. iron, 2·5—4 per cent. silica, and 0·02 per cent. phosphorus; limonite ores: 50—53 per cent. iron, 1—8 per cent. silica, and 0·035—0·01 per cent. phosphorus. Good, natural ports allow large steamers to load rapidly.

*Silver Ore of Milo.*—Silver was discovered in Milo and in the neighbouring isles of Kinolo and Polino about 10 years ago. In 1890 the Government prevented a company, having a concession to work lead-silver mines, from further exploiting these silver deposits, and ordered an examination by Government engineers, which is briefly resumed in the following:—

In these islands there exist in several places ventilar masses of heavy spar, intermixed clay, surrounded by clay and decomposed trachyte. These masses are embedded in fresh trachyte. The heavy spar, clay, and trachyte carry silver. It is estimated that there is no less than 10,000,000 tons of this ore. The silver is unevenly distributed, and the ore is not rich, averaging about 164 grains per ton (5½ oz.). Some assays have given as much as 4,000 grms. per ton.

The engineers being of the opinion that large quantities of ore averaging 250 grms. per ton could be profitably worked, the Government in February 1893 offered to grant a lease to the highest bidder to mine 150,000 tons within 15 years. It was easy to foretell that under these conditions and with the low price of silver no one would undertake to mine 8-oz. ore.

*Magnesite.*—This mineral holds an important position. Its occurrence in nature as magnesium carbonate appears to be rather limited, and nowhere else can it be found in such workable quantities as in Greece. The composition of the ore is as follows:—Magnesium carbonate, 96—98 per cent.; silica, 1—1·5 per cent.; alumina, 0·5—2 per cent.; calcium carbonate, 0·5—1·5 per cent.; iron carbonate, 0·3—0·5 per cent. The manufacture of bricks from burnt

magnesite was first carried out in Styria, Austria, but for some years past there has been an establishment at Eubœa. After many experiments and difficulties on account of the high temperature necessary (above the melting point of platinum) to burn the magnesite to a terrefactive substance, they succeeded about the middle of 1893 in carrying on the operations continuously. The maximum compressibility of magnesite is at 1,800° C., with a diminution of 80 per cent. in volume. The "Chamotteskine" and "Dinas bricks" used in the construction of the furnace (Hoffmann's circular) were unable to withstand the heat; now the magnesium bricks are used.

The specific gravity of these compact bricks is 2·64, and their composition is: Magnesium carbonate, 93·25—96·25 per cent.; calcium carbonate, 1·5—3·00 per cent.; silica, 1·5—2·5 per cent.; iron oxide and alumina, 0·75—1·25 per cent.

Emery is found in several of the Greek islands, but chiefly in Naxos, where it has been exploited for a long while, and occurs in boulders in crystalline limestone of the Archæan age. These mines could very easily compete against those of Asia Minor, situated between Smyrna and Ephesus, as they are purer, containing, before undergoing any cleaning, 68—70 per cent. corundum against 65 per cent. of the Smyrna deposits. The old method of fire-setting is still used on account of the difficulty of boring, even with the hardest steel. The price of emery in blocks at the coast of Naxos is 65 francs per metric ton; loads of at least 300 tons can be obtained, but on account of the bad ports it is difficult and expensive to ship such large blocks. Between the years 1869—1886 the quantity of Naxos emery produced was 41,344 metric tons, valued at 1,809,220 dols. From 1869 to 1889, the Government supplied emery at the fixed price of 218·80 francs at Naxos. Since then the competition of the Smyrna mines has brought the price down, as stated above, to 65 francs.—*Engineering and Mining Journal.*

## RUBBER PRODUCTION IN ASSAM.

According to the *Calcutta Englishman* for the 7th February, rubber is the most important of the minor forest products of Assam. It has yielded a considerable annual revenue to the Forest Department, obtained through the licensing of contractors, or *mahaldars*, who purchase the sole right of tapping trees, and practically within certain limits a monopoly in the foreign imported rubber trade. The revenue, however, has not been regarded as satisfactory during recent years, and owing to the illicit tapping operations carried on by the hill tribes, and the great difficulty of adequately protecting the Government rubber forests, it was decided in 1892 to discontinue the mahal system. In its place, a duty of 12 rupees per maund was imposed on all rubber, whether of home or foreign origin, obtained from Government forests or imported across the border, and this change promises, in the opinion of the conservator, to work very satisfactorily. There was some difficulty at first in explaining the new order of things to

the traders interested in rubber, and the exports during the first few months consequently showed a decrease as compared with those under the old system. There is every indication, however, that the trade is rapidly recovering itself.

## CHANGES IN U.S. PATENT OFFICE RULES.

In some recent changes in the "Rules of Practice" for the United States Patent Office, Rule 64 has been repealed. It read as follows: "The first step in the examination of an application will be to determine whether it is, in all respects, in proper form. If, however, the objections as to form are not vital, the examiner shall proceed to the consideration of the application on its merits, and in such case he must, if possible, in his first letter to the applicant, state all his objections, whether formal or otherwise, and until the formal objections are disposed of, further action will not be taken upon the merits without the order of the Commissioner." Instead of this the following rule has

been adopted: "Where the specifications and claims are such that the invention may be understood, the examination of a complete application and the action thereon will be directed throughout to the merits, but in each letter the examiner shall state or refer to all his objections. Only in cases presenting patentable substance will requirements in matters of form be insisted upon." The meaning of this seems to be that while an examiner may still specify in incorrectness in form as one of the reasons for rejecting an application, specifications or drawings will not be sent back for correction unless the examiner believes, after inspection, that there is some patentable point in the application.—*Engineering and Mining Journal*.

#### JOHANNESBURG SULPHURIC ACID WORKS.

The sulphuric acid manufactory recently erected near Johannesburg by a party of English capitalists, at a cost for plant of 55,000*l.*, is capable of producing 2,000 tons of acid per annum. The sulphur is obtained from pyritic

concentrates purchased from the mining companies. All the sulphur but 1 per cent. is extracted, and the oxidised ore is then sent on to extracting works for the recovery of its gold contents. The demand for sulphuric acid is increasing daily, and its price per lb., when taken in large quantities, as is done by the chlorination works, is less than that of the imported acid without the duty, which is 1*d.* per lb.—*Chemist and Druggist*.

#### CHEMICAL MANURES IN THE UNITED STATES.

In the United States the manufacture and consumption of chemical fertilisers has increased rapidly ever since the opening of the South Carolina deposits; fully one-half of the product is consumed in the cotton States, but as the rich soils of the north and west are gradually being exhausted, the use of fertilisers in those sections is increasing. The following tables show the production and consumption of fertilisers in the United States since 1888:—

	1888.	1889.	1890.	1891.	1892.	1893.
	Tons.	Tons.	Tons.	Tons.	Tons.	Tons.
Alabama.....	45,000	43,000	40,000	55,000	40,000	45,000
Florida.....	15,000	18,000	20,000	25,000	20,000	35,000
Georgia.....	170,000	185,000	200,000	230,000	175,000	280,000

Texas.....	10,000	10,000	12,500	10,000	5,000	10,000
Virginia.....	60,000	65,000	70,000	80,000	55,000	50,000
West Virginia.....	30,000	25,000	25,000	30,000	25,000	25,000
New England States.....	83,000	110,000	105,000	120,000	100,000	105,000
Western States.....	70,000	80,000	75,000	80,000	75,000	80,000
Middle States.....	210,000	370,000	350,000	300,000	305,000	285,000
Total.....	975,500	1,190,000	1,195,000	1,340,000	1,070,000	1,225,000
Production.....	980,000	1,230,000	1,250,000	1,320,000	1,365,000	1,350,000

Prior to 1888 the estimated production was 1,020,000 tons in 1885; 1,099,500 tons in 1886; and 975,000 tons in 1887. In 1862 Great Britain manufactured 200,000 tons of chemical manures, and in 1890 800,000 tons. The production for 1893 is estimated at 850,000 tons, about one-half being consumed in the United Kingdom and the remainder exported.

The world's supply of crude phosphate and guano as given by the best official sources is as follows:—South Carolina, 560,000 tons; Florida, 425,000 tons; Belgium, 400,000 tons; France, 400,000 tons; West Indies, guano, 30,000 tons; South America, guano, 45,000 tons; Russia, 70,000 tons; Germany, 50,000 tons; Spain, 40,000 tons; England, 30,000 tons; Canada, 15,000 tons; Norway, 20,000 tons; and North Carolina, 2,000 tons; total, 2,087,000.

The countries of Europe are estimated to have produced during 1893 the following amounts of acid phosphates:—France, 440,000 tons; Belgium, 275,000 tons; Germany, 550,000 tons; Holland, Sweden, and Norway, 150,000; Italy and Switzerland, 100,000; other countries, 100,000.

#### THE VALUATION OF MANURES.

A very useful guide for purchasers of manures and feeding stuffs has just been issued by the Highland and

Agricultural Society, in the shape of a scale of unit values to be used in determining a fair price, full instructions and illustrations of how to make the necessary valuations being appended. The manures are classified as follows:—

**Fish Guano.**—Finely ground, and containing not more than 3 per cent. oil. **Frey-Bentos Guano.**—(a.) Meat meal, free from horn, yielding over 11 per cent. nitrogen. (b.) Mixed scrap, yielding 6 to 7 per cent. nitrogen and 30 to 40 per cent. phosphates. **Bone Meal.**—(a.) 90 per cent. passing  $\frac{1}{8}$ -in. sieve. (b.) Coarser. Genuine bone meal contains 45 per cent. to 55 per cent. phosphates, and from  $4\frac{1}{2}$  per cent. to  $5\frac{1}{2}$  per cent. ammonia. The better qualities contain little or no fat. **Steamed Bone Flour.**—Ground to flour and containing about 60 per cent. phosphates and about 2 per cent. nitrogen. **Dissolved Bones.**—Must be pure, i.e., containing nothing but natural bones and sulphuric acid. **Dissolved Compounds.**—Including 'dissolved bone manures' and all special manures consisting of ingredients mixed together and dissolved as a whole. The 'average' units should be used in valuing ordinary well-made dissolved compounds. If the manure is of superior manufacture and of high concentration, the units used should be above the average; if of inferior manufacture, or of low concentration, the units used should be below average. In valuing such manures for associations the

units employed must be specified. Mixtures.—To be valued according to the unit values (as given below) of the ingredients of which they are guaranteed and also found to be composed, with an addition of from 5 to 10 per cent., according to the fineness of their manufacture. Thomas-Slag and Ground Phosphates.—Fineness of grinding is of paramount importance. The coarsest kind used should be so finely ground that 80 per cent. passes through a sieve of 10 000 holes per square inch.

#### Unit Values for Season, 1894.

—Chemical Trade Journal.

#### THE OUTPUT OF PLATINUM.

The total platinum output in the Ural mines in 1893 was 11,196 lb., against 10,038 lb. in 1892. The average annual output for the last 10 years has been 7,848 lb., that of 1893 being the greatest quantity ever obtained.—*Chemist and Druggist*.

#### THE COPPER ORES OF PERSIA.

A. F. Stahl. *Chem. Zeit.* 18, 3—4.

Up to the last 200 years the copper used in Persia was all produced in the country. Only the richer oxidised ores were smelted, ores of 3 to 5 per cent. being non-visible, were left by the miners. The old slags contain 1 to 3 per cent. of copper. The present production is uncertain, but the royalties paid to the Government show it to be considerable. There is little prospect of any extensive works being established, as, excepting near the Caspian, where, on the northern slopes of the Elburs mountains, wood and coal are available for fuel, or on the Persian Gulf (in neither of which regions is there sufficient evidence of important deposits), the cost of carriage would be prohibitive.

Particulars are given of many deposits visited by the author during the last three years.

The district of Anarek is rich in minerals. It is composed of recent limestones resting on ancient eruptive rocks and crystalline schists which have been broken

through by trachytic masses of tertiary age. Water and fuel are scarce, but copper and lead are smelted with charcoal made from the bushes found in the desert. Mining, together with camel-breeding, has supported a population of some 2,500 people, probably for centuries.

To the east of Senman, about 18 kilom. from the petroleum wells, carbonate and oxide of copper occur as an impregnation in clay slate, the mineralised stone assaying 5 per cent. Should the borings now in progress (for petroleum) succeed, the deposits would certainly be worth working, as sheet copper could be used for the transport of the oil.

About 15 kilom. to the east of Berta Agere, at the foot of the Sefid Kuk mountains, are two veins of copper pyrites from 3 to 4 in. in width, which the writer looks upon as payable deposits. The veins occur at the contact between porphyritic rock and jurassic limestone, and chalcopryite is associated with fluor- and calcspar. Coal is found in the vicinity, and communications both with the coast and the interior are comparatively good. In conclusion he says that though Persia appears to be rich in copper ores, the workable deposits are few and far between.—J. H. C.

## Monthly Patent List.

\* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

#### APPLICATIONS.

6551A. T. G. Hall. An appliance for breaking down crust in gas producers. Complete Specification. Filed March 19. Date claimed March 28, 1893.

5686. T. Lohnstein. An improved float for determining the absolute weight and specific gravity of solid and liquid bodies. Complete Specification. March 19.

5877. F. M. Robertson, W. S. Miller, and H. S. Fearon. Improvements in the process of and apparatus for evaporating or drying. March 21.

5925. G. Seagrave, J. H. Pickup, and L. Moritz. Improvements in apparatus for heating air or other gases. March 21.

6013. J. Alty. See Class XVII.

6176. J. E. Tolson and G. Tolson. A new or improved automatic hydro-extractor. March 27.

6462. K. C. Edmunds. An improved compound or mixture for freezing or chilling. March 31.

6495. E. Hermite, E. J. Paterson, and C. F. Cooper. A process for protecting iron pipes from corrosion by passage of electrolysed chloride solutions employed as disinfectants. March 31.

6953. A. G. Ogilvie. An improvement in kilns for burning lime or calcining other minerals. April 7.

7019. T. Oxley. Improvements connected with furnaces and relating to means for dealing with the products of combustion. April 9.

7027. L. Wagner and J. Marr. New or improved process and apparatus for purifying liquids. Complete Specification. April 9.

7033. F. E. Whitham. Improvements in depositing tanks for separating solids from liquids. April 9.

7235. D. McGill. An improved method of and means for the compression of air or other gases. April 11.

7305. J. G. Hall. An improved brewing-pan or copper for the boiling of worts used in breweries and distilleries, applicable to steam-boilers and other similar uses. April 12.

7318. T. Wheeler. An improvement in metallic thermometers and barometers. April 12.

7326. E. Hesketh and A. Marcet. Improvements in flasks or cylinders for containing gases under pressure or liquefaction or the like. April 12.

7388. E. G. Scott. Improvements in evaporating apparatus. April 13.

#### COMPLETE SPECIFICATIONS ACCEPTED.\*

1893.

8646. C. Huelser.—From A. Bloch. Process and appliance for mixing gases with liquids, especially carbonic acid, with water for baths and the like. April 4.

9147. J. Bouvier. Improvements in filters. April 18.

10,216. T. Ledward. An improved cooling apparatus for fluids. April 11.

1894.

2588. J. Nagel. Apparatus for distilling and sterilising water. April 11.

4094. S. C. Hauberg. Improvements in centrifugal liquid separators. April 11.

### II.—FUEL, GAS, AND LIGHT.

#### APPLICATIONS.

6152. H. Fourness. Improvements in the process of and apparatus for manufacturing water-oil gas. March 27.

6693. I. I. Gugenheimer. Improvements in heating gases for metallurgical furnaces. April 3.

6706. J. Parkes and J. Parkes. Improvements in gas-carburetting apparatus. April 4.

6737. J. Braunschield. Process for changing asbestos-fibre into an incandescent body for incandescent gas-light. April 4.

7019. T. Oxley. See Class I.

7179. J. Hodgkinson. A new and improved method of heating brine or similar substances. April 11.

7237. W. O. Felt. Improvements in the manufacture of gas. April 11.

7243. L. Parent. Improvements in the continuous manufacture of anhydrous metallurgic coke. April 11.

7372. M. Bernstein and A. Silbermann. Improvements in and relating to incandescent gas lighting. Complete Specification. April 13.

7482. S. A. Johnson. Improvements in the use or employment of hydrocarbon or other suitable oils, and in the method of burning same in firegrates, stoves, ranges, furnaces, or the like, for heating, cooking, and such like purposes. April 14.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1892.

23,497. E. Wardell and J. H. Evers. Improvements in apparatus for washing the gaseous products escaping from boiler and other furnaces, and for increasing the draught in such furnaces. March 28.

1893.

4037. H. Aitken. Improvements in and apparatus for obtaining cyanogen, cyanides, and other products from carbonaceous matter, or substances containing ammonia or nitrogen, or compounds thereof. April 4.

6515. E. Smith. Improvements for the consumption of smoke and waste gases in furnaces. April 4.

6551. T. G. Hall. A process and appliance for electrically treating gaseous and other bodies, a new compound gas made by such process, and apparatus for such producing and consuming said gaseous product. April 4.

7605. J. Smith. A retort and apparatus connected therewith for the purpose of converting coal-tar into gas for illumination and other purposes. April 11.

1894.

81. F. Kempster. An apparatus for the utilisation of mineral oils for heating purposes. April 11.

4719. E. Fleischhauer and M. Bernstein. Improvements in and relating to the manufacture of gas. April 18.

## IV.—COLOURING MATTERS AND DYES.

## APPLICATIONS.

5709. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of new colouring matters. March 19.

5711. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of colouring matters and materials therefor. March 19.

5712. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co., Germany. The manufacture or production of new azo-colouring matters. March 19.

5722. J. V. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. Improvements in the manufacture of colouring matters of the alkylated induline series. March 19.

5853. Brooke, Simpson, and Spiller, Limited, and A. G. Green. A new direct-dyeing yellow colour for cotton, and the process for its manufacture. March 21.

5870. J. Grime. A new or improved method of oxidising indigo blues and the like, and apparatus employed therefor. Complete Specification. March 21.

6004. F. Muhlert. Manufacture of yellow and orange colouring matters from  $\beta$ -resoreyllic acid. Complete Specification. March 22.

6197. B. Willeox.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of new azo-colouring matters. March 27.

6198. B. Willeox.—From F. von Heyden, Nachfolger, Germany. Improvements in the treatment or purification of commercial toluol-sulpho-amide. March 27.

6894. J. C. Mewburn.—From La Société Anonyme pour l'Exploitation des Procédés de Zebrowski, France. The manufacture of a new colouring matter particularly adapted for use in dyeing and printing. April 6.

7044. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation, Germany. Manufacture of colouring matters of the induline series. April 9.

7046. C. D. Abel.—From A. Fischesser and Co., Germany. Manufacture of 1 naphthylamine 3, 6, 8 trisulpho acid from 1 nitronaphthalin 3, 8 disulpho acid. April 9.

7422. J. Baruch and A. Goldsobel. Improvements in and connected with the manufacture of colouring matters. April 14.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

9895. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of new sulpho acids and derivatives thereof. March 28.

9972. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of colouring matters and processes for dyeing and printing therewith. March 28.

11,556. A. Ashworth and J. Burger. Improvements relating to the production of colouring matters. April 18.

11,902. T. R. Shillito.—From J. R. Geigy. Production of azo colours. April 11.

1894.

3886. W. E. Heys.—From Sandoz and Co. Improvements in the production of colouring matters dyeing with mordants. April 11.

4629. H. Inray.—From The Basle Chemical Works. Manufacture of a new dioxynaphthalene monosulpho acid and of colouring matters therefrom. April 11.

4630. H. Inray. From The Basle Chemical Works. Manufacture of a new dioxynaphthalene monosulpho acid and of colouring matters therefrom. April 11.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

## APPLICATIONS.

5718. H. Rous and G. N. West. A new or improved process for rendering textile materials waterproof and damproof. Complete Specification. March 19.

5952. J. Mackenzie. Improved means for the preparation of ramie fibre. March 22.

6032. F. W. Oliver. Improvement in treating cotton, linen, and silk fibres and threads with celluloid. March 22.

7093. J. Hargreaves. Improvements in the manufacture of ornamental woven fabrics. April 10.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

6007. A. E. Newman, R. E. Newman, and J. Newman. Improvements in the treatment of fibrous materials and in the means or apparatus employed therein. March 28.

7104. A. E. Newman, R. E. Newman, and J. Newman. Improvements in the treatment of flax and like fibrous material and in the means or apparatus employed therein. April 4.

22,808. J. C. Pennington and W. O. Allison. Improvements in or relating to the "retting" of fibres. April 18.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

## APPLICATIONS.

5951. S. Fisher, A. Mellor, and G. Wolfenden. Improvements in machinery or apparatus for cleaning and lustreing dyed or undyed yarns of silk, cotton, or other fibrous substances. March 22.

6054. H. Lange and R. Homberg. Improvements in or relating to bleaching, mordanting, dyeing, steaming, and analogous processes, and apparatus therefor. March 22.

6484. B. Thies. Dyeing apparatus for textile fibres. March 31.

6521. B. Cawthorn and J. P. Cornett. Improvements relating to apparatus used in the process of breaking and bleaching fibrous materials. April 2.

6673. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the process of obtaining coloured designs or patterns on indigo-dyed materials. April 3.

6803. A. Baummeister.—From P. Francois, France. An improved steaming or bleaching process for hemp or other textile materials and articles made therefrom. April 5.

6887. C. F. Cross and E. J. Bevan.—From C. Bealle, United States. A process for marking indelibly on paper, fabrics, and like receptive material. April 6.

7011. W. H. Hughes and S. F. Hughes. Improved process for scouring, cleansing, bleaching, and disinfecting wool and other fibres or fibrous materials. Complete Specification. April 9.

7133. W. McNaught. Improvements in or applicable to machinery for scouring and washing wool and other fibrous materials. April 10.

7135. A. Blanchon and A. Allegret. An improved process for printing indigo on fabric and yarn. April 10.

7197. E. Potter and Co., Limited, and A. Hunzinger. Improvements in printing upon calicoes or other woven fabrics and in apparatus employed therefor. April 11.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

10,327. J. Smith. Improvements in or connected with dyeing, tinting, sizing, and bleaching, or similarly operating upon textile fabrics or fibres and other materials. April 4.

15,531. G. A. J. Schott.—From E. Lauhe. Improvements in the method of bleaching cotton cloths and other materials, and in apparatus employed therein. April 18.

### VII.—ACIDS, ALKALIS, AND SALTS.

#### APPLICATIONS.

5808. J. D. Darling and H. C. Forrest. Improvements in producing nitric acid and metals from nitrates. Complete Specification. March 20.

5830. A. E. Hetherington and E. K. Muspratt. Improvements in the manufacture of ferrocyanide of potassium or of sodium from sulphocyanide. March 20.

5832. A. E. Hetherington, F. Hurter, and E. K. Muspratt. Improvements in the manufacture of cyanide of sodium or of potassium from their ferrocyanides. March 20.

5895. G. Webb, jun., and G. Webb, sen. Improvements in the manufacture of chlorine gas and caustic soda. March 21.

6426. T. Craney. Improved method and apparatus for manufacturing caustic soda. Complete Specification. March 30.

6445. C. R. Illingworth and D. Arthur. See Class XVIII. B.

6621. J. B. Readman. Improvements in obtaining cyanides and ferrocyanides. April 3.

6925. W. McDonnell Mackey and J. F. Hutcheson. Improvements in making potassic cyanide. April 7.

7179. J. Hodgkinson. See Class II.

7300. C. P. Shrewsbury, F. L. Marshall, and J. Cooper. Improvements in the method of and apparatus for obtaining sulphate of lead from galena. April 12.

7413. W. Garroway. Improvements in the manufacture of caustic soda and potash, and of nitric and sulphuric acids. Complete Specification. April 14.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

6044. L. O. Helmers. Improvements in obtaining sulphonic acids and sulphonic-like compounds free from inorganic salts from the neutralised product of the action of sulphuric acid upon mineral and similar oils, and particularly hydro-carbons artificially or naturally sulphurated. March 28.

7264. F. M. Lyte. Improvements in the production of chlorine and refined lead, and in the recovery of the silver the lead contains. April 11.

11,040. A. Brand. Improvements in the manufacture of chlorine. April 11.

1894.

4791. H. Wachter. A bleaching preparation or mixture applicable also for other purposes. April 11.

### VIII.—GLASS, POTTERY, AND EARTHENWARE.

#### APPLICATION.

6261. Chance Brothers and Co., Limited, and J. E. Scott. Improvements in tank furnaces used in the manufacture of glass. March 28.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

8758. W. W. Pilkington. Improvements in apparatus for forming molten glass into sheets. April 11.

15,411. M. Rosenthal and R. Walter. Improvements in the production of variously coloured designs, drawings, or pictures on porcelain, glass, or ceramic objects.

22,362. J. H. Bale. Wafer china mosaic. April 4.

### IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

#### APPLICATIONS.

6168. W. Horne. Improvements in the construction of fireproof buildings, and rendering existing buildings fireproof. March 27.

6552. J. H. Blakesley. Improvements in fireproof floors, roofs, girders, joists, and the like. April 2.

6662. W. F. F. Bevis. Improvements in and relating to building blocks. April 3.

6832. J. Kirby. Improvements in road pavings. April 5.

6890. G. S. Cory and J. R. Casbay. Improvements in paving for roads and streets. April 6.

#### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

7211. G. Gin. Improvements in the manufacture of cement. April 11.

10,044. T. L. Banks. Improvements in fireproof floors, ceilings, and the like, partly applicable to other forms of floors, ceilings, and partitions. April 4.

10,045. T. L. Banks. Improvements in fireproof framing for partition and other walls. March 28.

12,227. T. L. Banks. Improvements in fireproof structures for ceilings, floors, and roofs. April 11.

1894.

3803. T. D. Harries. An improved artificial stone. April 4.

## X.—METALLURGY, MINING, ETC.

## APPLICATIONS.

3790. J. A. Mayo. Apparatus for separating metals from and purifying lead. March 20.

3808. J. D. Darling and H. C. Forrest. See Class VII.

3831. A. E. Hetherington, F. Hurter, and E. K. Muspratt. Improvements in and apparatus for the production of alloys of sodium or potassium with lead. March 20.

5934. W. Perkins. Improved means for extracting metals from their ores. March 21.

6693. I. I. Gugenheimer. See Class II.

6743. E. Bonchill. Improvements in an apparatus for, or connected with, puddling raw, cast, or pig iron. April 4.

6783. H. G. Richardson. Certain improvements in the manufacture of iron and steel and other metals, and in apparatus to be employed in the said manufacture. April 5.

6791. C. A. Allison.—From C. Bell and W. S. Bell, United States. Improvements in methods and apparatus for smelting or reducing aluminium ores. April 5.

6914. P. Manhes. Improvements relating to the manufacture of nickel and cobalt. Filed April 6. Date applied for December 9, 1893, being date of application in France.

6916. R. F. Hall. Improvements relating to the casting of metals. April 6.

6974. C. de E. Llatas. Improvements in the manufacture of steel. April 7.

6984. P. Manhes. Improvements relating to the treatment of nickel and cobalt ores. Filed April 7. Date applied for January 16, 1894, being date of application in France.

7380. S. Taylor. A new or improved solder for soldering aluminium and alloys of aluminium. April 13.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

6137. A. J. Smith. Improvements relating to the pickling of metals and alloys to remove oxide and other impurities from the surface thereof. April 4.

7264. F. M. Lyte. See Class VII.

7791. C. T. J. Oppermann. An improved process for the preparation of iron or steel plates for nickel or other plating. April 11.

10,367. O. G. Goodman. A process of leaving malleable or soft portions of steel articles in hardening and tempering. April 4.

10,463. H. J. Kirkman. Improvements in and relating to pickling iron and steel plates and other articles previous to tinning or galvanising. April 11.

10,699. E. Hammesfahr. Apparatus for cooling or hardening objects of metal, alloys, and the like between plates, moulds, dies, or rollers. March 28.

12,946. D. P. G. Matthews. Improvements in and connected with metallic moulds, and in the method of using such moulds for casting brass or bronze alloys. April 18.

21,352. L. W. Mallasee. An improved method of casting steel and apparatus therefor. April 11.

1894.

2527. E. Norton. Improvements in the art or process of manufacturing tin orterne plate. March 28.

2629. W. P. Thompson.—From J. J. C. Smith and E. C. Smith. Improvements in or appertaining to casting metals. April 11.

4980. W. P. Thompson.—From O. Nicolai. A new or improved solder for soldering aluminium, aluminium alloys, and other metals. April 18.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

## APPLICATIONS.

5721. C. Smith.—From G. Jorgensen, Norway. New or improved process and apparatus for the electrolytic decomposition of common salt. March 19.

6016. L. A. P. Liénard and H. E. A. Liénard. Improvements in the methods of effecting the electrolysis of saline solutions. Complete Specification. Filed March 22. Date applied for September 22, 1893, being date of application in France.

6241. F. A. Rhead and H. G. Coleman. A method of depositing and affixing metals by electricity upon a medium which is fastened upon ceramic objects by burning in a kiln. March 28.

6402. G. E. B. Pritchett, T. W. Pritchett, and A. G. Gold. Improvements in electric accumulators. March 30.

6497. E. Hermite, E. J. Paterson, and C. F. Cooper. Improvements in apparatus for electrolysing chloride solutions employed for disinfecting. March 31.

6917. H. Guthrie. Improvements in apparatus for electrolytical purposes. April 6.

6975. A. J. Smith and H. J. Wright. Improvements relating to the manufacture of plates or electrodes for electric accumulators or secondary batteries, and to machinery or apparatus therefor. April 7.

7094. W. J. S. Barber-Starkey. Improvements in and connected with secondary electric batteries. April 10.

7145. S. O. Cowper-Coles and Sir B. W. Walker, Bart. Improvements in or connected with the electro-deposition of metals or metallic compounds and the treatment of deposited metals or compounds. April 10.

7165. E. J. Clabbe and A. W. Sonthey. Improvements in secondary voltaic batteries. April 10.

7205. A. F. B. Gomess. A new or improved process for the electro-deposition of aluminium and aluminium alloys. April 11.

7206. A. F. B. Gomess. A new or improved process for the electro-deposition of aluminium and aluminium alloys. April 11.

7311. B. A. N. Dorez. Improvements relating to secondary batteries. April 12.

7467. A. J. Marquand and E. Hancock. Improvements in primary electric or secondary batteries. April 14.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

6000. B. H. Thwaite. Improved methods for effecting the electric fusion of steel and its alloys. March 28.

6751. E. Placet and J. Bonnet. Improvements in the extraction of chromium by electrolysis, applicable also to the production of chromium alloys. April 11.

6780. V. C. Doubleday.—From M. Sussmann. Improvements in secondary batteries. March 28.

7711. P. Schoop. Improvements in electrical accumulators or secondary batteries. April 18.

10,042. F. King. Improvements in and apparatus for the manufacture of plates, grids, or supports for secondary batteries. April 18.

11,122. A. E. Peyrusson. Improvements in secondary batteries or accumulators. April 18.

11,973. Siemens Brothers and Co., Lim., and E. F. A. Obach. Improvements in apparatus for electrolysis of water. April 4.

1894.

3710. A. J. Boulton.—From C. Cudell, I. Cudell, and M. Cudell. Improvements in galvanic batteries. April 18.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

### APPLICATIONS.

5821. F. J. Machalski. Improvements in apparatus for extracting fat and glue. Complete Specification. March 20.

7126. F. Walton. A process and apparatus for oxidising frying oils. April 10.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893

9315. W. N. Hartley and W. E. B. Blenkinsop. Improvements in or relating to the treatment of oils for refining, deacidifying, and boiling the same. April 18.

9882. G. Pommerhantz. Improved process of producing consistent and semi-consistent fats and oils without applying heat. March 28.

10,664. J. Weir and G. Weir. Improvements in separating oleaginous or fatty matters from boiler feed-water or other water. April 4.

12,817. E. Watel. A process of improving and preserving oils and fats. March 28.

## XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

### APPLICATIONS.

5779. S. Banner. Improvements in or relating to treating copal for making gum copal varnish. March 20.

5856. H. P. Scott. Improvements in compositions or paints for coating iron, steel, or metal structures to preserve them from fouling and corrosion. March 21.

6002. J. E. Williams. A new or improved anti-salt paint. March 22.

7129. R. Matthews. Improvements in the manufacture of white lead. April 10.

7465. A. Angell. Improvements in the manufacture of oil paints and compositions from carbonised or calcined iron-stone or iron ore. April 14.

### COMPLETE SPECIFICATIONS ACCEPTED.

1892.

23,572. S. Z. de Ferranti and J. H. Noad. Improvements in the manufacture of white lead. March 28.

1893.

8368. R. Irvine. Improvements in the manufacture of paint. March 28.

11,727. W. C. Nangle. An improved paint or paint-like composition. April 18.

12,266. R. Hutchison. Improvements in treating or preparing gutta-percha and rubber for various purposes. April 18.

## XIV.—TANNING, LEATHER, GLUE, AND SIZE.

### APPLICATIONS.

5821. F. J. Machalski. See Class XII.

7324. H. A. Leverett and G. J. B. Buckley. An improved process of rapidly making leather. April 12.

### COMPLETE SPECIFICATIONS ACCEPTED.

1893.

10,445. J. Pullman and A. Pullman. Improvements in machinery or apparatus for treating skins in the manufacture of leather. April 4.

1894.

3615. E. H. Lewis. Improvement in the art or process of waterproofing leather and in the compounds employed in same. March 28.

3626. E. H. Lewis. Improvement in the art or process of waterproofing leather. March 28.

## XV.—AGRICULTURE AND MANURES.

### APPLICATION.

5692. W. Newton. Improvements in the manufacture of phosphatic and nitrogenous fertilisers. March 19.

## XVI.—SUGARS, STARCHES, GUMS, Etc.

### APPLICATION.

6223. L. E. Asser. Improvements in the treatment of feculent matter used in the manufacture of glucose. March 27.

### COMPLETE SPECIFICATION ACCEPTED.

1894.

3782. E. Langen. Improvements in refining sugar. March 28.

## XVII.—BREWING, WINES, SPIRITS, Etc.

### APPLICATIONS.

6013. J. Ahy. Improvements in refrigerators for cooling wort or other liquids and apparatus connected therewith. March 22.

6293. A. D. Watson. Improvements in cooling yeast and in apparatus therefor. March 29.

7456. L. I. N. Norman. Improvements in the manufacture of brewing syrup. April 14.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

10,132. J. Pikhart. An improvement in the manufacture of beer. April 4.

10,263. K. Michel and M. Frank. Improved method of and apparatus for collecting the carbonic acid generated during the fermentation of beer or wine. April 11.

12,391. O. Oldham. An improved mixture for the manufacture of non-intoxicating beer and stout. April 11.

## XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

## APPLICATIONS.

*A.—Chemistry of Foods.*

6010. H. H. Lake.—From F. Delangle, France. Improvements relating to the preservation of alimentary and other organic substances. March 22.

6106. W. F. Maclaren and T. B. Rawlins. Improvements in the manufacture of condensed milk. March 24.

6257. W. Flowers. Improvements relating to the admixture and treatment of certain ingredients for the production of a new article of food. March 28.

7009. A. Girling. Wafer table jelly. April 9.

7055. E. Markham. An improved process of preserving eggs. April 9.

*B.—Sanitary Chemistry.*

5792. R. C. Sayer. Improvements in sanitation. Complete Specification. March 20.

5819. J. Schmeiser and A. Billig. An improved process and apparatus for impregnating air with the essence of fir wood. March 20.

6049. J. B. Alliot. Improvements in apparatus for the treatment of offensive and infected matters. March 22.

6159. M. F. Purcell. Utilisation of sewage. March 27.

6318. H. S. Chapman. An improvement in the treatment of sewage discharging into the sea. March 29.

6445. C. R. Illingworth and D. Arthur. A new method of treating sewage and other liquid organic refuse for the extraction and fixation of ammonia. March 31.

7053. F. E. Whitham. Improvements in depositing tanks for separating solids from liquids. April 9.

7056. J. F. Foveaux. Treatment of sewage by evaporation, heating, and ventilating. April 9.

*C.—Disinfectants.*

6243. G. C. Kinloch. The use of picric acid as an insecticide, antiseptic, and disinfectant. March 28.

## COMPLETE SPECIFICATIONS ACCEPTED.

*A.—Chemistry of Foods.*

1893.

8726. H. Trillich. Improvements in or relating to the preparation of substitutes for coffee. April 11.

*B.—Sanitary Chemistry.*

1894.

4195. H. H. Lake.—From Seaburg and Johnson. Improvements relating to the burning of sulphur for disinfecting purposes. April 18.

*C.—Disinfectants.*

1893.

11,679. I. S. McDougall and J. T. McDougall. Improvements in disinfectants. April 18.

11,807. C. T. Kinzett. Improvements in sulphur candles and their holders. April 18.

11,944. I. S. McDougall and J. T. McDougall. Improvements in insecticides and anti-fungoids. April 18.

12,400. I. S. McDougall and J. T. McDougall. Improvements in fumigants. April 18.

## XIX.—PAPER, PASTEBOARD, Etc.

## APPLICATIONS.

6221. G. Fehrenbach and L. Prud'hou. An improved process for producing artificial whalebone and method of forming same into strips. Complete Specification. March 27.

6301. J. Craig. Improvement in the manufacture of paper. March 29.

6468. F. Duffett. An improvement in the manufacture of blotting and other absorbent and porous papers. March 31.

6522. J. P. Cornett. Improvements in or connected with the manufacture of pulp for paper-making. April 2.

7486. L. Munk. Improvements in the manufacture of paper and the like. April 14.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

## APPLICATIONS.

6033. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering, Germany. The manufacture of certain bodies suitable as remedies. March 22.

6190. F. Krafft and A. Roos. Manufacture of acid esters, phenol and other ethers by means of aromatic sulphonic acids. Complete Specification. March 27.

6800. L. Lederer. A new process of producing oxybenzylic alcohols and their homologues. April 5.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

10,701. J. Meikle, jun. Apparatus for extracting substances by volatile solvents. April 18.

12,942. H. Baum. Improvements in the manufacture of ortho-halogen-phenol and the production of pyro-catechine therefrom.

## XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

## APPLICATIONS.

6256. J. R. Hueto. Improvements in photography called "photo-sculpture." March 28.

6690. E. J. Tobin and F. G. Benet. Improved actinic print and improved method of producing same. Complete Specification. April 3.

6740. F. W. T. Krohn. Improvements in emulsions for photographic printing purposes. April 4.

## XXII.—EXPLOSIVES, MATCHES, Etc.

11,502. E. Kubin. Improvements in or relating to explosives. April 11.

## APPLICATIONS.

5939. H. Priester. An improved compound for use in the manufacture of matches. Complete Specification. March 21.

6700. A. Price. An improved explosive and fuze-warmer. April 4.

7051. A. V. Newton.—From A. Nobel, France. Improvements in the preparation and utilisation of tempered explosives. April 9.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

8392. G. Kynoch and Co., Lim., and E. Jones. Improvements in cordite-loading machines. April 18.

## XXIII.—ANALYTICAL CHEMISTRY.

## COMPLETE SPECIFICATIONS ACCEPTED.

1893.

7547. C. R. C. Tiehborne and C. J. Thompson. Improved apparatus for the determination of butter fat in milk. April 11.

# THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 5.—Vol. XIII.]

MAY 31, 1894.

[Non-Members 80/- per annum; Members 21/- per Set of extra or back numbers; Single Copies (Members only) 2/6.]

## The Society of Chemical Industry.

### Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S. ....	1881—1882.
Sir Frederiek Abel, Bart., D.C.L., F.R.S. ....	1882—1883.
Walter Weldon, F.R.S. ....	1883—1884.
W. H. Perkin, Ph.D., F.R.S. ....	1884—1885.
E. K. Muspratt ....	1885—1886.
David Howard ....	1886—1887.
Prof. James Dewar, F.R.S. ....	1887—1888.
Ludwig Mond, F.R.S. ....	1888—1889.
Sir Lowthian Bell, Bart., F.R.S. ....	1889—1890.
K. Rider Cook ....	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S. ....	1892—1893.

## COUNCIL FOR YEAR ENDING JULY, 1894.

*President:* E. C. C. Stanford.

### Vice-Presidents:

Sir F. A. Abel, Bart., F.R.S.	Dr. W. H. Perkin, F.R.S.
Horace T. Brown, F.R.S.	Prof. J. Emerson Reynolds,
H. Brunner.	M.D., D.Sc., F.R.S.
Wm. Crowder.	John Spiller.
Sir John Evans, K.C.B., F.R.S.	Prof. T. E. Thorpe, F.R.S.
Dr. F. Hurter.	Sir John Turney.
E. K. Muspratt.	

### Ordinary Members of Council:

R. Forbes Carpenter.	C. C. Hutchinson.
Prof. Frank Clowes, D.Sc.	John Pattinson.
Dr. C. Dreyfus.	Manning Prentice.
Thos. Fairley.	Boverton Redwood.
C. A. Fawcitt.	A. Gordon Salamon.
Prof. G. G. Henderson, D.Sc.	T. Tyrer.

With the Chairmen and Secretaries of Sections.

### Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

### Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

*General Secretary:* Charles G. Cresswell.

*Offices:* Palace Chambers, 9, Bridge Street, Westminster, S.W.

## THE JOURNAL.

### Publication Committee:

The President.

A. H. Allen.	Prof. A. K. Huntington.
L. Archbutt.	F. Hurter, Ph.D.
G. H. Bailey, D.Sc., Ph.D.	C. Clarke Hutchinson.
Joseph Bernays, M.I.C.E.	Wm. Kellner, Ph.D.
H. Brunner.	Ludwig Mond, F.R.S.
E. Rider Cook.	B. E. R. Newlands.
W. Y. Dent.	John Pattinson.
Chas. Dreyfus, Ph.D.	W. H. Perkin, Ph.D., F.R.S.
Sir John Evans, K.C.B., F.R.S.	H. R. Procter.
Percy Gilchrist, F.R.S.	Boverton Redwood.
John Heron.	John Spiller.
D. B. Hewitt, M.D.	Win. Thorpe.
David Howard.	Thomas Tyrer.
Prof. J. J. Hummel.	

### Editor:

Watson Smith, University College, London, W.C.

## NOTICES.

In accordance with the provisions of Rule 18 of the By-Laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list, will retire from their respective offices at the forthcoming Annual General Meeting.

Dr. T. E. Thorpe, F.R.S., has been nominated to the office of President; and Mr. E. C. C. Stanford has been nominated Vice-President under Rule 11.

Mr. John Calderwood, Dr. C. Dreyfus, Dr. A. Dupré, F.R.S., and Prof. W. A. Allen, F.R.S., have been nominated Vice-Presidents under Rule 8; and Mr. Win. Thorpe has been nominated an Ordinary Member of Council under Rule 17, in the place of Dr. C. Dreyfus, nominated a Vice-President.

Mr. C. A. Fawsitt has been nominated an Ordinary Member of Council under Rule 24, and the Treasurer and Foreign Secretary have been nominated for re-election to their respective offices.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

*Extract from Rule 18:*—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

#### ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in Edinburgh on the 18th, 19th, and 20th July next. An influential Reception Committee has been formed, and an outline programme (subject to modifications) appears below. Tickets of membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

#### *Draft Programme.*

Wednesday, July 18th.

10.30 a.m.—Council Meeting, Queen Street Hall.

11 a.m.—General Meeting, Queen Street Hall, Presidential Address, &c.

For the afternoon the following visits have been arranged:—

1. Galleries and Museums.
2. Dalmeny Palace.
3. Roslyn.
4. Granton. — Garden Party, by invitation of the Chairman.

8 p.m.—Reception and Conversazione in the Industrial Museum, by invitation of the City of Edinburgh.

Thursday, July 19th.

The following works and places of interest will be open for inspection:—

1. Dalkeith Palace and Ground.—His Grace the Duke of Buccleugh.
2. Floor Cloth and Linoleum Manufacture.—Messrs. J. Barry, Ostlere, and Co., Lim., Kirkcaldy.
3. Printing, Colour Printing, and Bookbinding.—Messrs. Thos. Nelson and Sons, Parkside Works.
4. Paper-Making Machinery.—Messrs. Jas. Bertram and Son, Leith Walk Foundry.
5. Paper Works (Rag and Esparto).—Messrs. A. Cowan and Sons, Lim., Valleyfield Mills, Penicuik.
6. Paper Works (Esparto, &c.).—Messrs. Jas. Brown and Co., Lim., Esk Mills, Penicuik.
7. Soap Manufacture.—Messrs. Wm. Taylor and Co., Broughton Soap Works.
8. Printing Ink, Oils, &c.—Messrs. A. B. Fleming, Caroline Park.
9. Flint Glass Manufacture.—Messrs. Jno. Ford and Co., Holyrood Glass Works.
10. Ornamental Glass Works.—Messrs. A. D. Jenkinson, Abbey Hill.
11. Brewing.—Messrs. W. McEwan and Co., Lim., Fountain Brewery.

12. Brewing.—Messrs. Jas. and Thos. Usher, Park Brewery.
  13. Distilling.—The North British Distillery Co., Lim.
  14. Oils and Paraffin Shale.—The Broxburn Oil Co., Lim., Broxburn.
  15. Gas-Making and Refuse Destructor.—Edinburgh Gas Works, Powderhall.
  16. Coal Mines, Brick and Fireclay Works.—The Lothian Coal Co., Lim., Rosewell.
  17. Shipbuilding.—Messrs. Ramage and Ferguson, Lim., Leith.
  18. Leith Docks.—Peter Whyte, Esq., Superintendent.
- 7.30 p.m.—Annual Dinner, Waterloo Hotel, Edinburgh.

(The above list is subject to modification.)

Friday, July 20th.

Excursions from Edinburgh to—

1. Aberdeen.
2. St. Andrews and Perth.
3. Melrose, Abbotsford, and Peebles.

9 p.m.—Smoking Concert.

#### BANKERS' ORDERS.

For the convenience of Members, the Treasurer has arranged with the Bankers of the Society that they shall collect subscriptions from Bankers in town and country; and Members, who have not already done so, are invited to fill up and sign the Banker's Order enclosed with the December number of the Journal, which should then be sent to the Honorary Treasurer, Mr. E. Rider Cook, East London Soap Works, Bow, E.

#### INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

We are requested by the Foreign Office to state that an International Congress, under the patronage of the Belgian Government, will open in Brussels on the 4th August next, in connection with the Antwerp Exhibition, on the subject of Applied Chemistry.

The work of the Congress will be divided into four sections corresponding to those of the Belgian Chemists' Association, viz.:—Sugar, Agricultural Chemistry, Food-stuffs, and Biological Chemistry.

Those who desire to attend the Congress should apply to M. Sachs, 68, Rue d'Allemagne, Brussels (Sugar and Agricultural Chemistry), or to M. H. van Laer, 15, Rue de Hollande, Brussels (Adulteration of Foodstuffs and Biological Chemistry), who will forward full particulars on application.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

## LIST OF MEMBERS ELECTED 23rd MAY 1894.

Bristed, John, c/o Messrs. Kemp & Co., Lim., Bombay, India, manager.

Brown, Wm. A., Tudor Oil Works, Port Elizabeth, Cape Colony, oil works manager.

Burmeister, M. W. Edw., Bodestrasse 40, Hamburg, Germany, merchant.

Dewar, John A., Melrose House, Perth, distiller (Lord Provost of Perth).

Ellis, Geo. Beloe, 6, Westbourne Terrace, Hyde Park, W., solicitor and patent agent.

Ford, Jno. Humphrey, Holyrood Glass Works, Edinburgh, flint glass manufacturer.

Gray, Parker, 77, Dartmouth Park Road, London, N.W., oil and tallow merchant.

Hally, Col. Jno., Ruthven Tower, Auchtermarder, N.B., manufacturer.

Holliday, Thos., Lunelough Hall, Huddersfield, aniline dye manufacturer.

Macadam, Stevenson, jun., Analytical Laboratory, Surgeon's Hall, Edinburgh, analytical chemist.

MacIlwaine, A. W., Stoneferry, Hull, oil manufacturer.

Mackenzie, Robt. W. R., Huntingtowerfield, Perth, N.B., bleacher.

Marshall, J. Burt, Luncarty, Perth, N.B., bleacher.

Moneriff, John, Elmside, Balhousie, Perth, N.B., glass and ink manufacturer.

Overend, F. L., Blairlodge School, Polmont Station, N.B., teacher of chemistry.

Pullar, Herbert S., Rosebank, Perth, N.B., dyer.

Purdie, Prof. Thos., 14, South Street, St. Andrews, N.B., professor of chemistry.

Richardson, Wm. H., c/o The Newsky Thread Manufacturing Co., St. Petersburg, Russia.

Schönzeler, Jno., c/o Messrs. C. Gross & Co., 9, Mincing Lane, E.C., metallurgical chemist.

Shepherd, Jas., Rossend Castle, Burntisland, N.B., linoleum manufacturer.

Simomura, T. K., c/o C. and J. Favre Brant, Kawaguchi, Osaka, Japan, technical chemist.

Veitch, Geo., Chemical Works, Crieff, N.B., manufacturing chemist.

Watson, C. Heron, Bullionfield Paper Mill, by Dundee, paper manufacturer.

## CHANGES OF ADDRESS.

Ashworth, L., 10 St. Anne's-on-Sea; The Orchard, Manchester Road, Bury, Lancashire.

Babington, P., 10 Weymouth; 36, Dudley Road, Tunbridge Wells, Kent.

Bailey, W. H.; Journals to Sir W. H. Bailey—address as before.

Baker, Theodore, 10 Emporium; Oakland, Bergen Co., N.J., U.S.A.

Bentz, E., 10 Manchester; The Elms, Handforth, Cheshire.

Bray, D., 10 Mumbles; Broadmoor Chemical Works, Cloderford, Gloucestershire.

Burghardt, Dr. C. A.; Journals to Fern Cottage, Alderley Edge, Cheshire.

Carter, W. Chas., 10 Abercorn Road; 19, Short Strand, Belfast, Ireland.

Chapman, Spencer; all communications to 36, Mark Lane, E.C.

Chemical Society of Paris; Journals to M. A. Bebal, 111, Boulevard de Port Royal, Paris.

Colman, Dr. H. G., 10 Noel Road; 23, Stirling Road, Edgbaston, Birmingham.

Croft, A., 10 Old Kenton; Henry Street, Bridgeford, Nottingham.

Duncan, A. W., 10 Stockport; 17, Penn Street, Higher Broughton, Manchester.

Eastwick, Jos. H., 10 Pittsburg; 2202, Venango Street, Philadelphia, Pa., U.S.A.

Fleming, J. Arnold, 10 Tunstall; 136, Glebe Street, Glasgow.

Glendinning, Tom A.; Journals to The Brewery, Leeds.

Haynes, D. O., 10 Detroit; P.O. Box 1183, New York City, U.S.A.

Heslop, Oliver; Journals to Allhusen's Works, Gateshead-on-Tyne.

Hooper, Ern. F., 10 Silvertown; Elmleigh, Beckenham, Kent.

Knaggs, A. B., 10 Morley; 65, Belle Vue Road, Leeds.

Lindemann, G., 10 Hamburg; Neulengbach bei Wien, Austria.

McKillop, Jno., 10 Singapore; 96, Haldon Road, Wandsworth, S.W.

Mawdsley, W. H., 10 Chester; G.P.O., Rockhampton, Queensland.

Meacham, C. S., 10 Earl Street; Pettridge, Maidstone, Kent.

Russell, Rt. Hon. J. A., Lord Provost of Edinburgh; Journals to Rt. Hon. Sir Jas. Russell—address as before.

Shalleross, A., 10 City Road; Corbett Street, Bradford, near Manchester.

Shalleross, T. H., 10 Fairfield; Corbett Street, Bradford, near Manchester.

Slater, Sydney H., 10 Highbury; Poste Restante, Johannesburg, S.A.R.

Thackray, R. B., Journals to Leather Works, Newlay, Leeds.

Wilkinson, Dr. Saml. W., 10 Whaley Bridge; The Grove Co., Lim., 17 Coleman Street, E.C.

Wills, J. Lanson, 10 Ottawa; c/o Dr. F. Wyatt, 12, Old Slip, New York, U.S.A.

Wingham, A., 10 Torquay; 112, Warwick Street, Pimlico, S.W.

Withaus, Dr. R. A., 10 55th Street; 303, West 77th Street, New York, U.S.A.

Wyatt, Dr. F., 10 Park Place; 12, Old Slip, New York, U.S.A.

Young, W. C., 10 Forest Gate; Normanhurst, High Road, Romford, Essex.

## CHANGES OF ADDRESS REQUIRED.

Clark, Jno., 10 Great Brook Street, Birmingham.

Isaac, T. W. P., 10 Cavendish Place, Brighton.

Whitehouse, E., 10 Smethwick, Birmingham.

## Deaths.

Arrol, Jas., jun., 8, Firpark Terrace, Dennistoun, Glasgow.

Cameron, R., Wellpark House, Bathgate, N.B.

## London Section.

THE CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE, W.

*Chairman:* Wm. Thorp.

*Vice-Chairman:* W. Crowder.

*Committee:*

E. J. Bevan.	F. G. Adair Roberts.
W. G. Blagden.	A. Gordon Salamon.
C. C. Hutchinson.	G. N. Slosar.
T. A. Lawson.	F. Napier Sutton.
R. Messel.	T. Tyrer.
B. E. R. Newlands.	Frank Wilson.
W. Ramsay.	C. R. Alder Wright.

*Hon. Local Secretary:* John Heron,  
74, North Side, Clapham Common, S.W.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman:* B. E. R. Newlands. *Committee:* E. Grant Hooper, H. de Brossenthal, E. O'Neill, S. Rideal, A. Shearer, and Wm. Thorp.

SESSION 1893-94.

Meeting held Monday, May 7th, 1894.

MR. WM. THORP IN THE CHAIR.

## THE ELECTROLYSIS OF FUSED SALTS.

BY CLAUDE VAUTIN.

I wish to couple the name of Mr. H. K. Picard with mine in this matter as a slight recognition of the manner in which he, assisted by Mr. Hopkins, has helped me in the investigation I have been engaged upon in the above subject.

It is my intention to bring under the notice of the Society notes of some of the work that has been done in my laboratory during the past year. I regret that I did not at the outset devise a less comprehensive title for the paper; the commercial electrolysis of fused salts is indeed a subject exceedingly wide, and I purpose to limit my remarks to the decomposition of the fused chlorides of sodium and potassium, trusting at some future date to submit some further notes.

It may be interesting if I explain why I directed my attention to the electrolysis of the fused salts of the alkaline metals rather than their solutions in water. After having endeavoured for a considerable time to devise a method of economically decomposing a solution of chloride of sodium in water, the use of a mercury cathode of somewhat novel form was worked out. You will understand that the surface tension of mercury is so great that it will permit a horizontal layer of from  $\frac{1}{16}$ th to  $\frac{1}{2}$  an inch in thickness to be sustained on a perforated plate or open mesh of certain sized perforations or openings without falling through. In Fig. 1 I have illustrated in somewhat exaggerated form the effect on the under surface of mercury when supported by a perforated plate.

With this application of mercury as a cathode, a vat was constructed in which was an inner tray, the bottom of which consisted of a finely perforated non-conducting material, or, if the bottom was made of metal, it was coated with an insulating material so as to ensure complete insulation, otherwise the retaining plate would become part of the cathode, which would be undesirable. Upon the

bottom of this inner trough a layer of mercury was supported and made the cathode, and carbon in the outer vessel the anode. On passing the current, sodium was

Fig. 1.

deposited upon the under side of the mercury, forming an amalgam which, in consequence of its lightness, rose rapidly to the surface of the mercury, where, coming in contact with water, the latter was decomposed with the formation of sodium hydrate.

Fig. 2 represents diagrammatically the form of apparatus. A represents a vat constructed of suitable material; D the

Fig. 2.

inner or mercury cathode containing tray; B finely perforated plate for retaining the mercury; C conductor dipping into the mercury; E carbon anodes; F chlorine exit.

This method worked fairly well, but, nevertheless, I could not bring myself to believe that any of the methods for decomposing solutions of sodium chloride known to me would, in any great measure, take the place of the existing chemical means of producing chlorine and soda, for all or any of the following reasons:—

1, the vastness of the plant required; 2, the comparatively low conductivity of solutions; 3, the disintegration of the carbons, and the several other well-known difficulties and objections in connection with the electrolysis of solution of NaCl. The foregoing remarks do not refer to the electrolysis of a solution of KCl.

I then turned my attention to the use of fused alkaline chlorides as electrolytes, but the literature on the subject and the results obtained by many investigators, together with our own work, exposed so many difficulties, whenever it was attempted to recover the alkaline metal either by distillation or by collecting under bells, that it was decided, if possible, to obtain sodium or potassium in the form of an alloy.

When endeavouring to obtain the alkaline metals by distillation or any method where a solid cathode was used, the yield fell far below theoretical quantity; and it appears that either the statements that have been frequently made

as to the existence of the subchloride of the alkali metals must be true, or else these metals must be dissolved in an electrolyte of their fused chlorides.

In 1873 Werdermann obtained letters patent in England for a process wherein he claimed the formation of sodic subchloride by electrolysis fused salt with carbon electrodes. By this process, when it was estimated that a considerable percentage of sodium subchloride had been formed, the contents of the vessel were permitted to cool, treated with water, when it is stated that sodium hydrate was formed according to the formula :—

It was also proposed that the subchloride should be used as a reducing agent, and, as an illustration, the reduction of cryolite was mentioned according to the following formula :—

I mention these facts as showing that previous investigators had, in all probability, been confronted with a low yield of sodium when attempting to electrolyse its fused chloride.

Referring to the recovery of the alkaline metals by distillation during electrolysis, I am of opinion, even supposing that anything like the theoretical quantity of metal could be obtained, that a very considerable amount of the electrolyte would distil over with the metal; thus it would be difficult to obtain the metal in a state of purity and free from the electrolyte.

In attempting to collect the metal under bells, as has been lately suggested, considerable difficulty has been experienced in preventing the bells, if composed of non-conducting refractory material, from becoming destroyed, both by the action of the electrolyte and the freed alkaline metal. When iron bells have been used, insulated on the inside, trouble has been experienced in preventing the insulation from breaking down and the outside of the bell becoming part of the cathode, thus causing a portion of the alkaline metal to be liberated at the anode, where recombination with the chlorine would cause a great waste of energy.

With a view to overcoming these difficulties, it was decided to obtain the sodium in the form of an alloy: lead naturally suggested itself as a most convenient metal with which to form this alloy because of its low fusing point, its indifference to a solution of sodium hydrate, its stability under either fused  $\text{Na}_2\text{O}$  or its hydrate, and its cheapness.

I requested Mr. Picard to make an alloy by adding sodium to lead; and this alloy containing upwards of 20 per cent. of sodium was heated in a crucible under fused  $\text{NaCl}$ . I was quite prepared to find, upon examining the contents of the crucible after it had been removed from the furnace and allowed to cool, that the sodium had distilled out, or had been acted upon by the fused chloride. Such was not the case, for it was found upon careful examination that little, if any, sodium had been removed from the lead at the temperature at which the operation had been conducted.

This experiment, followed up by one in which molten lead was made the cathode, using melted sodium chloride as the electrolyte, gave results confirmed by subsequent investigations, that warrant me in stating that the question of economically producing chlorine and soda or potash by the electrolysis of their fused chlorides has, in a measure, been solved. The experiment was conducted in the apparatus represented by Fig. 3. A represents a crucible, B a lining of magnesite, C molten lead, D carbon anode, E iron conductor dipping into the lead at C, F non-conducting tube to insulate the iron E from the electrolyte G, G molten salt, H exit for chlorine. Upon passing the current of about 100 amperes, the lead alloyed with the liberated sodium, the surface of the lead being the true cathode. The experiment was run until about 8 per cent. of sodium to the weight of lead had been deposited. After allowing the crucible to cool, it was broken, and the alloy removed; it was brittle, and acted with energy on water. The salt was not alkaline, intimating that no sodium had been removed from the lead with the formation of any basic chloride. The operation,

from start to finish, was uniform; no variation of resistance was noted. Indeed why should there be any disturbing element, for the conditions of the electrolyte are constant

Fig. 3.

and, provided the anodes stand up and the sodium is alloyed as liberated, how are the conditions to vary?

A number of experiments were made in the apparatus represented by Fig. 4, the lettering being the same as in Fig. 3, with the addition of A', which is an inner crucible containing the lead cathode. By this arrangement the removing of the alloy was facilitated, for, after having run for a stated period, the inner crucible could be removed by a pair of tongs and the contents either cast into a mould or allowed to cool down with the crucible, and removed by breaking. This method was economical so far as large crucibles were concerned. Subsequently, lined iron pots were used, as will be explained farther on. A fact of the utmost importance is the possibility of obtaining nearly the theoretical quantity of ions when working in this manner.

With the view of ascertaining in a practical manner the exact difference in the resistance of a solution of sodium chloride and the same chloride in a fused condition, the following experiment was conducted.

Two crucibles were selected, practically corresponding in shape and size; in the bottom of each an equal quantity of lead was carefully melted and the insulating tubes containing the cathode conductor were inserted.

In one, a saturated solution of salt was placed; in the other salt was melted; in both cases the depth of the electrolytes was the same. The anodes were of the same size and character and placed in exactly corresponding positions in both crucibles, that is to say, the distance from the lead cathode and depth of immersion were the same, and the experiment demonstrated that, at least five times the quantity of current could be passed through the fused salt as is possible

through the solution at the same pressure. At 3.5 volts, 1.4 amperes passes through the solution, and at 2 volts, 4 amperes passes through the fused salts. Although the foregoing experiment gave results considerably in favour of fused salt, so far as unit of plant is concerned, in practice a much larger ratio in favour of the fused salt is possible; for in any wet installation it would not be possible to so advantageously arrange the relative position of anode and cathode as in this experimental run, to say nothing of the

Fig. 4.

extra resistance, in systems where diaphragms are used. In our own work when using the mercury cathode, as previously explained, and under the most favourable conditions as to the position of the anodes, it was not possible to pass more than  $\frac{1}{2}$ th of the current at the same voltage, area for area, as when using the fused electrolyte.

Naturally, to a great extent, the ultimate purpose to which the alloy is to be put will determine the form of the apparatus; if the alloy is to be used as a source of metallic sodium or potassium, sodic or potassic oxide or hydrate, then, at present, I am inclined to the use of steel pots lined with magnesite, except at the bottom, for a reason to be explained further on. Fig. 5 represents what I mean.

The lettering to E represents the same parts as in Fig. 3. Here, the pot being of iron or steel and being insulated to a point below the surface of the lead, any convenient part of it can be made the cathode connection; it is shown here at E. L represents a pot in which lead can be melted and run into A when required by pipe J. K pipe from bottom of A to caustic pot L. Starting with a given

quantity of lead in A, the alloy is formed, and, when deemed rich enough, the valve in K is opened and the alloy run into L, where it is submitted to the action of steam, by which means the sodium of the alloy is converted into its corresponding hydrate.

A fresh supply of lead is run into A from I when the alloy is tapped into L from time to time. The lead in L, after the alkaline metal has been removed, is taken back to I for further use.

You will note that the pot itself is made the cathode connection, but, in consequence of the lining above referred to, coming down below the surface of the molten lead, the surface of the lead is thus caused to be the true cathode; the metal of the pot forming a most convenient means of conducting the current from the lead. If the sides of the pot were not protected by a neutral insulating material, not only the surface of the lead but also the pot itself, or rather that portion of the pot in contact with the molten salt, would become a part of the cathode. The covers of the pots, instead of being constructed of fragile refractory material, can be constructed of iron protected from the action of the chlorine by the following means:—

The iron cover is dipped into molten salt, when a film or layer is frozen, so to say, on it, provided the iron is removed from the molten salt soon enough; and, the temperature to which the cover is exposed not being high enough to melt the coating of salt thereon, a most effective means of protecting the iron from the action of the liberated chlorine is obtained.

Iron is attacked by heated dry chlorine, in spite of the often repeated statement to the contrary.

Objection has been made to the use of cast-iron pots in which to melt salt, for, if heated from the outside and the salt permitted to come in contact with the inside, the salt, to a considerable extent, sweats through; but, if cast-iron pots lined with a neutral material down to a point below the level of the lead are used, this objection falls to the ground; however, in my opinion, steel is much to be preferred as material for the construction of the pot. The question of melting the salt either by external means by the combustion of gas or coal, or, internally, by means of electricity, is not quite a settled matter; there are a number of pros and cons, that can be settled only by actual work; personally, I lean towards maintaining the salt in a molten condition by means of the current, for, by so doing, the life of the apparatus will be considerably prolonged, and greater simplicity in the construction of the plant ensured.

Melting in basic lined muffle furnaces is advocated by those well versed in the salt-cake furnace operations, but there are, at present, many objections and difficulties that I foresee, which, however, may be overcome by chemical engineers. I refer particularly to the difficulty of collecting the chlorine and of so arranging the furnace that the principle of having several decomposers in series can be advantageously applied.

A convenient form of apparatus for producing the alloy of potassium and sodium with lead, tin, &c., in small quantities is represented by Fig. 7. The lettering down to and including H represents the same as in Fig. 3.

The section of the furnace T is rectangular, with an exit for the products of combustion at U, and provided with an injector for gas or petroleum at V, the steel crucible A rests on and in the support W, at the bottom of furnace T. A cover X made in four sections containing a circular opening and resting on the sides of the furnace and extending in to the furnace far enough to cover the top of the crucible. Between the true cover Y and X is a space from which an opening H is provided as a means of exit for the chlorine. The true cover Y is provided with an aperture through which to insert the anode. To the bottom of the pot is connected an iron pipe marked Z. The pipe Z passing through the bottom of the furnace and connected with the bottom of the pot affords a ready means of removing the alloy from time to time, and, as can be easily understood, from reference to the sketch, the alloy in Z could be caused to set by circulating water through the pipe M, which is tightly coiled round Z, to remove the alloy; or a valve in Z can be used instead of the setting method. When it is desired to remove the alloy, the water can be shut off from

M, when the alloy will melt and run into vertical ingot mould N. The potassium or sodium can be protected from the oxidising influence of the air by burning some hydrocarbon in the vicinity of the exit pipe H and the mouth of the mould, say at O. You will note that the pot, or any portion of it, can be made the cathode connection.

This method of removing the alloy can be used with advantage in larger installations. In working the process the temperature at the bottom of the pot, or rather that portion of the pot surrounding the alloy, should be kept as low as is possible consistent with the fluidity of the metal; therefore it is well that the support or rest for the pot L should continue for several inches above the bottom of the pot.

In actual work it is found expedient to limit the percentage of the alkali metal in the alloy to from 10 to 20 per cent., the use to which the alloy is to be put regulating the percentage.

The sodium or potassium can be removed from the lead in the form of a hydrate by any of the following methods:—

A, by tapping the alloy from the decomposing vessel into moulds as previously described, allowing to cool, removing from mould, breaking in pieces (which can be done with facility in consequence of its brittleness), placing in water, when, as can be easily understood, the hydrate of the alkaline metal is produced, fortunately the lead remaining in a condition in which it can be easily re-melted, without any serious loss; or the alloy is re-melted in an iron pot and

Fig. 5.

submitted to the action of steam, when fused caustic is produced, which can be ladled from the surface of the lead; or by arranging the apparatus as represented in Fig. 6, so that the lead forming the cathode in the decomposing vessel is connected by means of an iron pipe N to molten lead in an outer or separate pot M, where it is submitted to the action of steam, introduced by pipe P and, in consequence of the rapid diffusion of the sodium or potassium through molten lead, contained in the connecting pipe N, the lead in the outer pot becomes impregnated with the alkaline metal, which, coming in contact with steam, alkaline hydrates are formed in a fused condition and can be ladled or tapped out, and it is thus possible to have a continuous process of producing caustic alkali in a fused condition; the lead

simply acting as carrier of the alkaline metal from the decomposing pot to the caustic pot. O represents exit for hydrogen and excess of steam, R fused caustic, S outlet for caustic.

When it is desirable to remove the sodium from the lead in the form of sodic oxide, all that is necessary is to melt the lead sodium alloy under a layer of fused caustic soda according to the well-known reaction.

I refer to this reaction as being of considerable importance, for it is exceedingly probable from the result of some experiments lately made, that sodium peroxide can be manufactured by the oxidation of  $\text{Na}_2\text{O}$  so formed. The alloy can un-

Fig. 6.

doubtedly be put to other uses, for instance, the production of potassium cyanide or a mixture of sodium and potassium cyanide by decomposing the ferro salts. The lead alloy, in consequence of its brittleness, can be easily crushed, and, provided a small quantity of mineral oil is used during crushing, little if any loss of the alkaline metal by oxidation is experienced. The crushed alloy can be mixed with dehydrated ferrocyanide and the mixture submitted to heat, when the alkaline metal will take the place of the iron, the lead and iron settling out well from the fused cyanide. Being able to finely divide the alloy and thus intimately mix the sodium with the ferrocyanide, it appears that a more perfect reduction can be obtained than when unalloyed metallic sodium is used, in consequence of the difficulty of finely dividing and mixing that metal through the ferrocyanide.

Metallic sodium can, to some extent, be distilled in properly constructed retorts from its alloy with lead; this is an important matter, since it enhances the value of the process as a ready means for obtaining metallic sodium or potassium from chloride by means of electrolysis, and experiments are now being conducted with a view of working this out to a practical issue.

As to cost of decomposing a given quantity of salt, I think I cannot do better than refer you to the able paper of Messrs. Cross and Bevan, published in the Journal of this Society in December 1892. In small installations I feel inclined to suggest that the use of large gas engines

should receive attention. I had an interview with a representative of Messrs. Tangye on Monday last and, from the information given me by that gentleman, it appears that with producer gas large gas engines can be run with great economy, and I am informed that Mr. Parker is putting down a 200 h.p. gas-motor plant to drive dynamos in some electrolytic installation.

The voltage necessary to decompose the fused chlorides of the alkaline metals is just under 2.

By using pure NaCl and lead and decomposing the resulting alloy of Na and Pb by means of distilled water in silver dishes, it is possible to obtain sodium hydrate in as great a state of purity as can now be obtained in the market. I mean pure NaHO for laboratory purposes.

The anodes used are of gas carbon, but in order to ensure continuous working with the minimum of disintegration, it is necessary that the carbon should be submitted to the following treatment:—

The anodes boiled in a concentrated solution of sugar carefully re-carbonised and, when thus treated, appear to stand sufficiently well for all practical purposes. I have here an anode that has been in work for several months, and you can see by comparing the thickness of that portion of the carbon that has been in the electrolyte with that portion that has not, that little, if any, abrasion or loss has taken place. If the carbons are used without the above-named method or other pore-filling process, after running for a few hours, a considerable increase of resistance in the

Fig. 7.

circuit is noted, probably in consequence of chlorines being generated in, and remaining in, the pores of the carbon, thus causing the noticed increase of resistance, in fact an ordinary porous carbon after two hours' run becomes perfectly insulated, even under 10 volts pressure. That the life of gas-retort carbon in melted chloride is greater than in the corresponding solutions I am sure of. I most willingly admit that there are many points to get over, but when the great chemical engineering skill available in England is taken into consideration, I have no doubt as to the ultimate results.

#### DISCUSSION.

Mr. C. F. CROSS said he had listened to what he considered an extremely modest account of a departure in electrolytic practice which appeared of the greatest technical importance. He was not able to follow the author through his criticism of previous literature with regard to the electrolysis of fused salts. He had followed somewhat closely

the developments of electrolysis as applied to solutions, more especially solutions of common salt. Mr. Vantin evidently regarded that matter rather as ancient history, and could not have followed very appreciatively some of the developments which had taken place, more especially during the last eighteen months or two years. If he had not been so enamoured of his new discovery, he might have ascertained that the Le Snecr method, which he knew of as a more or less "laboratory process," had been running on strictly commercial lines now for nearly two years in the United States. Without going into details of production, he might state that 85 per cent. of efficiency was steadily realised on the commercial scale, and that all difficulties with regard to diaphragms and carbon anodes had been reduced to a highly satisfactory minimum, so that he thought they might congratulate those who were still working on the wet methods on having achieved a great deal in what appeared ten years ago to be a very far off problem. Mr. Vantin had mentioned the method of electrolysing salt solution with a

mercury cathode in which Kellner and himself appeared to have run a close race for priority. This was a philosophically interesting development, but there did not appear to be much prospect of realising anything like commercial results with this cathode. The continuous separation of the cathode from the electrolyte was also the subject of Hargreaves and Bird's patent of more recent date, whereby with mere purely mechanical appliances the same absolute separation of the sodium hydrate from the chloride was accomplished. Here, again, considering the low voltage at which this process was run, and the steady realisation of an efficiency certainly over 80 per cent., he would have formidable rivals to contend with. In reading his paper he had not given many details in point of measurements; possibly he had not gone far enough to ascertain these with precision. He gave a comparative estimation of the amount of current which could be passed—all other conditions being maintained equal—through a saturated solution of salt and through his fused salt, and arrived at a multiple of 5 in favour of the latter. He (Mr. Cross) was unable to traverse that statement, and accepted it with the reservation that all statements of this general kind were liable to error when all the factors were not distinctly stated and separated one from the other. He would like to know, as the next element of cost of production, the cost of the fusion of the sodium chloride and the cost of keeping it in a state of fusion. Of course, theoretically the amount of heat necessary for the fusion of sodium chloride was small, but when dealing with practical quantities those matters had to be taken into serious consideration. Those who were dealing with brine had the obvious advantage that they could operate directly on the product, whereas in dealing with a solid which had first to be mined in a more costly way and then fused, the initial cost in the cell would be greater, giving an advantage in favour of brine. Then there was the question of the chlorine, and he should like to know how he dealt practically with the chlorine, which was evolved at a very high temperature. Generally the technical public would require full comparative statements both of current measurements and chemical statistics in order to form a satisfactory judgment as to the relative cost of the dry and wet processes.

Mr. W. F. REID said he should also like to make a remark on what was said about the aqueous electrolysis. It seemed to him that keeping up this high temperature during the process must to some extent balance its economy. If he understood the author rightly, he claimed economy on the ground of the lesser amount of electricity required to effect decomposition. If that was so, of course it would be a question of the difference between the amount saved in that way and the amount of fuel expended in keeping up the high temperature. He was of opinion that in electrolytic processes for the production of caustic soda, there were at present two difficulties. One was the plant which was used, and the deterioration of that plant, and the cost of keeping it in order. That was only partially overcome, and was still a difficulty, in spite of the sanguine views expressed by some patentees with regard to their anodes. The other difficulty was the cost of the electricity itself. Even when the process worked smoothly one found oneself running very close indeed, as regards cost of production, with the old methods of producing caustic soda. With electricity at its present price, the margin in favour of electrolytic soda was not great, and it depended on economy of management, and having very good apparatus. When he referred to that point once before, a gentleman present, an engineer, said they could not hope to get cheaper electricity, because they had almost attained a maximum of efficiency. That referred really to the efficiency of the steam-engine, but perhaps at some future time electricity might be obtained without the steam-engine, and then, no doubt, caustic soda produced by the wet process or, perhaps, by this one, would be cheaper than caustic soda produced by chemical means. It also occurred to him that there might be a difficulty from the volatilisation of the lead as the process was conducted, and if so, special means would have to be devised, not only to keep that from entering the atmosphere

of the work-shop where the operations were carried on, but also to prevent the escape of free chlorine, which must be a great source of nuisance. Of course it might be made a source of profit, but he should like to hear whether that had been accomplished. Certainly the process as described would be classed amongst the dangerous industries. He should like to know the fusing point of the alloy of lead and sodium, and also whether the apparatus, Fig. 5, had been carried out in actual practice, for it appeared that there would be some difficulty in running the alloy between the two vessels, though perhaps this could be overcome if the fusing point were very low. With regard to the lining of crucibles with magnesia, he would suggest that it might be possible to employ crucibles made almost entirely of magnesia. He had, himself, in research experiments, made crucibles, which stood very well, of Portland cement. He mixed it, and burnt it very carefully after it had set, and found he got a fairly strong crucible to which a basic lining adhered very well. It would stand a temperature far higher than that used in these experiments. It seemed to him that on a large scale there was a great source of energy which might be further utilised in the decomposition of the raw material. With regard to the statement that no trace of lead could be found in the solution, that was entirely against his own experience. He should have thought that in the caustic soda solution produced by decomposition of lead and sodium even more than traces of lead would be found, and he should be glad to hear if the author had made a careful examination on that point.

Mr. J. SWINBURNE took exception to the author's statement that wet processes of electrolytic caustic and bleach manufacture would not pay. The assertion was too sweeping. There were too many processes before the public; some good, most bad; but the difference between the worst and the best was very small in comparison with the difference between any reasonable electrolytic method and the present chemical processes. The difference in expense was infinitely less than that between a badly managed limited liability company and a worse managed limited liability company.

Mr. Vautin said dynamo makers could not make low pressure dynamos. As a dynamo maker he would correct this statement. Dynamos could be made for any pressures that might be wanted. The reason why the vats were generally put in series is that if in parallel the copper leads would be too expensive. There was thus a disadvantage in using very low pressures.

Before discussing the merits of fixed salt and solution in making electrolytic caustic and bleach, he would point out that Mr. Vautin's excellent process had other openings. There is a large market for sodium, which could, no doubt, be largely filled by a sodium lead alloy. The alloy could, no doubt, be used for making cyanide of potassium and sodium from yellow prussiate of potash. This method had the advantage that, as potassium cyanide was estimated by its cyanogen, and the combining weight of sodium was low, one could make impure cyanide which would pass as 100 per cent. cyanide of potassium, or even higher. There was an increasing demand for pure cyanide of potassium, and also for sodium peroxide. Sodium oxide could of course be made by treating lead sodium alloy with a limited weight of water or steam; and the oxide may be peroxidised. Then there was a demand for sodium in the reduction of aluminium; and if the price were brought down the demand would probably increase. Then though chlorine attacks red-hot iron, if dry it does not attack cold iron. The chlorine from fused salt can therefore be cooled and stored and transported in iron or steel tube flasks in the liquid form. The saving due to this method of packing would be very considerable.

Coming down to the question of making caustic, he thought Mr. Vautin had laid too much stress on the purity of his caustic. It was a matter of pounds, shillings, and pence. If the removal of salt in the wet process added so many shillings a ton to the cost of manufacture, that must be taken into account, but that was all that was to be said. The cost of fusing the salt would, he thought, be nil, if done electrically from the inside. The surplus of the electrical

energy above the heat energy of combination must in any commercial process be amply above that necessary to heat the salt. The question of keeping in the heat was only a question of size of vat and of lagging. The contents of a vat altered to scale in all its dimensions varied as the cube of its dimensions, and its output varied between the square and cube, while the loss of heat varied as the dimensions only, so a size was easily reached above which the difficulty was to keep the vat cool. This method of heating overcame a very serious difficulty not mentioned by Mr. Vautin, namely, the wear and tear of the iron pots when heated externally. On the other hand, the cost of evaporating and finishing was very serious in the ordinary process. On the wet electrolytic process it might be less because there was more salt. In the wet process the waste power could not be utilised in the same way as in the electrolysis fused salt.

While on the subject of waste power he would make a digression on the calculation of what is called the "theoretical" electro-motive force from the heats of combination. There was seldom a paper or a book on electrolysis published in which the authors did not calculate the electro-motive forces necessary for decomposition by dividing the heats of combinations by constants. In the first place, writers generally took wrong figures to begin with. For instance: to find the electro-motive force necessary to decompose solution of sodium sulphate, they would take the figures due to burning metallic sodium in gaseous oxygen, which have nothing to do with the matter. This was a mere detail, however. The whole principle was wrong. It was shown by Helmholtz in 1882 that the heat of combination was only one term, and another must be taken; so that the ordinary method was quite wrong. Yet people still go on calculating what they call the theoretical volts. To publish such a calculation in 1894 brands a man as an electrolytic crank of the deepest dye.

A great deal was said about the price of electrical power. He had given the figure as a farthing per kilowatt hour, including depreciation and interest, at the Institution of Electrical Engineers a few years ago, and he thought this figure has been generally accepted by electrical engineers. The cost of energy must not be taken from central station figures, as the engines and boilers are there running under the worst possible conditions.

The CHAIRMAN said this was one of those processes in which it seemed to him the error came in the passage from the small scale to the large. He did not know whether Mr. Vautin could give any more definite figures, but if so they would be very important.

Mr. PARKER said the difficulty was much greater in dealing with sodium salt in solution than with potassium salt.

Mr. VAUTIN said in reply that he would first refer to the question of temperature and in his notes he referred to the question of maintaining a mixture of salts in a molten condition by means of an internally heated crucible by means of the current.

By a judicious mixture of the chlorides of the alkali metals it was possible to have a mixture of a very low melting point. He was sorry to have created an impression in Mr. Cross's mind that he assumed that all wet processes were ancient history; what he did say was referring to the wet process known to him; and he happened to know the Hargreaves process or principle, or one of exactly similar principle before he left Melbourne some seven years ago.

In addition to the reasons he had given he considered that the amount of doubt and uncertainty that attached to the wet processes, rightly or wrongly, rendered it very unlikely that there would be an immediate change from the chemical method of manufacture.

With regard to the criticism that he did not give the exact figures, he had said the proportion was five to one; he had the figures in the paper, but omitted them in reading. As a matter of fact in the wet process at  $3\frac{1}{2}$  volts, 1.4 amperes passed through the solution. On the other hand, just under 2 were needed in the dry, and 4 amperes passed,

which just made a difference of 1 to 5; and there was this difference in his favour, that with 2 volts he could not work the wet experiment at all, but required  $3\frac{1}{2}$ . As far as the cost was concerned, it was to a great extent the fact that they were able to work at very much lower voltage, and that compensated to a great degree the cost of keeping the salt molten. They could afford to use a portion of the electricity over and above that necessary to decompose a solution of salt for the purpose of keeping the salt molten. In fact, in a large operation the trouble would be to keep the temperature down, and in all probability it would be great economy to burn a little extra coal under the boiler and keep the whole of the electrolyte molten by means of the electric current. In that case the life of the plant would be considerably enhanced. With regard to the volatilisation of the lead, he could only say that such did not exist. Lead protected from the air was rather a fixed metal at a temperature much higher than that required for the operation. As for chlorine the one object was to lead it into a chamber in which there was finely-divided hydrated lime. The chlorine coming away from an apparatus on a large scale was not nearly so high in temperature as the hydrochloric acid from a salt-cake furnace. He had shown this small apparatus simply for the sake of giving a practical demonstration that the alloy could be formed. It was very different on a larger scale. Again, with regard to the cost, they had not to evaporate the solution of caustic nor a mixture of caustic soda and chlorine of sodium to separate them. His criticisms of the wet processes in no way referred to solutions of potassium chloride, but he thought he was right in saying that 90 per cent. of the wet electrolytic processes in the States or elsewhere were in connection with potassium salts. He knew that in potassium salts, advantage could be taken of the ease with which chlorate crystallised out from the electrolyte.

## THE TESTING OF HYDRAULIC CEMENTS.

BY W. HARRY STANGER, M.I.C.E., F.C.S., AND BERTRAM BLOUNT, F.I.C., F.C.S.

FOR a good many years past there has been a large and increasing amount of attention devoted to the testing and control of the quality of hydraulic materials of construction and especially of Portland cement. This can be traced to the failures that have occasionally occurred from not very obvious causes, in large and costly engineering undertakings, and proximately to the natural anxiety, on the part of engineers, thus engendered. Persistent technical research and the constant comparison of results obtained in the laboratory and testing room with those observed in actual work have improved the methods of testing, and increased the accuracy of the deductions that can be made from a properly executed series of tests, until at the present time no engineer using hydraulic cement who desires to be assured of the permanence of his work omits to obtain proof of the quality of the material by systematic testing and analysis.

The general methods of testing cement are too well known to warrant a lengthy description in this paper, but it may be permissible to indicate the methods which, among the many that appear in text books and technical journals, are of sufficient importance and general applicability to stand as representatives of modern practice. The following order will be found convenient.

**Fineness.**—The only method of ascertaining the fineness of cement that is in common use is that of sifting. It has been recognised comparatively recently that the coarser particles of an hydraulic cement, certainly all that remain on a sieve having 76 meshes per linear inch, and probably many that pass this sieve, are either wholly inert or so slow in setting as to be useless or even objectionable. The inertness does not arise from any chemical difference between the coarse "core" and the rest of the cement, but

from the fact that the surface presented by a coarse particle is relatively smaller than that by a fine particle, and the rate of attack by water in the process of setting is correspondingly diminished. It has resulted from the recognition of this fact that cement specifications now demand greater fineness than was formerly usual, and manufacturers have striven to comply with this demand by the use of improved grinding machinery, and by sifting the finished cement before putting it on the market. Not very long ago a residue of "10 per cent. on a 50" was regarded as indicating quite a fine cement, whereas "10 per cent. on a 76" is now in no way an uncommon requirement, and much cement is of still finer grade. The plan of specifying that not more than a certain residue of coarse core shall be left on a standard sieve is convenient, but possesses certain disadvantages. In the first place it offers no guarantee that a large portion of the cement may not consist of particles just small enough to squeeze through the meshes of the sieve, but still too coarse to possess much value as cement. This can obviously be remedied by adding to the specification a clause requiring that not only shall the cement leave no more than a certain amount of coarse core, but that it shall also contain not less than a certain amount of finely-ground matter, estimated by passage through the finest sieve in ordinary use, *e.g.*, that having 160 meshes per linear inch. When this requirement becomes general it will be time enough to consider whether the limit of the determination of fineness can be pushed with advantage beyond that set by a 160 sieve. In some special instances when it was desirable to have a means of separating the fine fraction of a cement isolated by sifting, into further fractions, we have successfully employed the plan of elutriating the material with a liquid incapable of acting chemically upon it, *e.g.*, turpentine, freed from dissolved water by distillation and drying over quicklime, or a mineral oil of low viscosity. Should it be found requisite to adopt any such method in the ordinary testing of cements, to discriminate between samples containing various proportions of "flour," it will become necessary to arrive at a standard method of applying the test to secure comparable results. The contingency is not, however, immediate, though the test is a useful one in certain cases.

Reverting to the customary method of determining fineness, only a few points claim notice. The first is that accidents in wiring or stamping sieves occasionally occur, and it is therefore prudent to verify the number marked upon the sieve by counting the wires, if need be, by the aid of a lens. The next is that a standard wire, as well as a standard number of meshes per linear or square inch, should be adopted, as otherwise sieves identical in title may give diverse results. The third relates to the manner of ascertaining the results of sifting. It is generally preferable to weigh the portion that remains on the sieve rather than that which passes through, as some loss from the latter is almost inevitable, sifting cement being a very dusty operation. It is probable that this canon holds good in the case of the determination of the "flour" of the cement, *i.e.*, the portion which passes through the finest sieve, an estimation by difference being for once in a way more trustworthy than a direct determination. Nevertheless, the direct weighing may be profitably used a check.

**Weight per Unit Measure and Specific Gravity.**—These properties of a cement are intrinsically distinct, but are frequently confused. The practice of making a determination of the weight per cubic foot, or more commonly weight per bushel, doubtless arose from the fact that a convenient method of bringing the weight and apparent volume of cement into commensurate terms is a necessity for engineers computing the requisite quantities of structural materials, as witness the wide use of the weight per cubic foot of the most diverse substances, from copper to asphalt. When it was observed that an apparent unit volume of cement varied in weight according to its quality, a natural attempt was made to deduce quality from weight per apparent unit volume. Hence the now standard requirement that a Portland cement shall weigh a specified number of pounds per bushel. As long as all cement was ground to about the same degree of fineness this system proved moderately effective, when made workable by the use of a standard hopper and measure for

the determination of the weight of a struck bushel, but as a demand for finer cement arose, it was found that the weight of 115 to 120 lbs. per bushel that once was easily reached, could no longer be readily attained. In short, the weight per bushel depends, other things being equal, on the fineness of the cement, and a sliding scale for the weight per bushel regulated by the specified fineness becomes necessary, transforming a test of simplicity and fair accuracy into one cumbersome and inexact. Fortunately, the whole difficulty is removed by the substitution of the determination of the specific gravity for that of the weight per bushel. The latter is properly retained for making a series of rapid tests capable of execution by any fairly intelligent person acting as inspector of cement at a works to ascertain that there is at least tolerable uniformity throughout a heap of many tons. The former can be best applied in the laboratory where the testing and analysis of the cement are carried out.

The average weight of fresh, fairly finely ground Portland cement (*e.g.*, leaving a 10 per cent. residue on a 76 sieve) is 108–110 lbs. per bushel. The specific gravity of the same sample will be about 3.15. The apparent specific gravity deduced from the weight per bushel is 1.37. The difference is so great that there is a large margin for an alteration of the weight per bushel by the closer packing of the cement particles, and it is easy to see how considerable an error may exist. The determination of the true specific gravity of cement is not free from pitfalls on its own account, especially when it is carried out—as is often the case—by comparatively unskilled persons with somewhat crude apparatus. Owing to the circumstance that hydraulic cements are necessarily acted upon by water, that liquid is obviously inadmissible for use in the determination of their specific gravity, and some fairly mobile and not very volatile liquid, such as petroleum or spirits of turpentine, must be substituted. It is of the first importance, whatever liquid be adopted, that it be perfectly dry. Mere freedom from turbidity is no guarantee that all water is absent. Complete dehydration must be secured by allowing the liquid to stand over good "fat" quicklime or similar dehydrating agent which is unacted on by the liquid itself. With regard to the method to be used, it may be said that the ordinary specific gravity bottle affords as accurate a result as can be wished, but necessitates a knowledge of the specific gravity of the liquid employed. The plan of determining this value for a large supply of the liquid, and using it for a series of determinations extending over a long time, is not to be recommended, as slight changes may occur on keeping (particularly in the case of turpentine, the specific gravity of which increases by re-refinement), and give rise to an appreciable error. On this account, and because of the necessity of operating at a standard temperature, the use of the specific gravity bottle is generally given up in favour of a volumometer, in which the displacement of a known weight of cement is read directly. The ordinary Schumann apparatus, consisting of a graduated glass tube ground into a bottle, is a rough apparatus of this kind. The apparatus is filled with turpentine or petroleum to the zero mark and a known weight of the cement, usually 50 or 100 grms., shaken in through a funnel down the graduated tube, the liquid displaced rising in the graduated tube, where its volume can be read. In this case the weight taken is fixed and the volume variable. A second instrument on the same principle, but in some respects preferable, is that shown in Fig. 1. Here the upper bulb is of known capacity (*e.g.*, 1,000 grains) between the fiducial marks A and B. The vessel is filled with liquid to the mark A, weighed, and cement is introduced until the level of the liquid reaches B, when it is weighed again. In this case, therefore, the volume is fixed and the weight variable.

An improved form of the Schumann apparatus which we were at one time in the habit of using, is that illustrated at Fig. 3.

A side tubulus carries a small thermometer, and the main reservoir is fitted to a broad wooden base to increase its stability.

In the two forms of Schumann apparatus the serious fault exists that the cement must be introduced after the liquid down a long tube, the natural result being that there is a great tendency for the cement to stick to the sides of the

tube and form obstructive plugs just at the surface of the liquid, which are sometimes difficult to dislodge. This evil cannot be overcome by an increase in the width of the tube without introducing a large reading error. Conversely, close reading is impracticable without so diminishing the

Fig. 1.

Fig. 2.

Fig. 3.

diameter of the graduated tube that the introduction of the cement becomes well-nigh impossible. The bulb form of apparatus illustrated in Fig. 1 is better in these respects, but necessitates two weighings in place of one.

For rapid routine work, we have devised an extremely simple form of volumenometer which is free from most of the defects of those generally made. It consists, as will be seen from Fig. 2, of a small flask very much flattened

in shape so as to ensure its stability, and provided with a short slender neck with fine graduations, not ground into the lower part of the vessel, but blown in one piece therewith.

The lowest graduation mark on the neck is not 0 but 14 cc., and the capacity of the flask to the first graduation mark is known and equals 64 cc. The instrument is used by running into it 50 cc. of turpentine from a pipette which has been accurately calibrated against the flask. As the turpentine is introduced by means of a pipette the neck of the apparatus is kept dry, and the known weight of cement (50 grms.) can be readily added through a small funnel without blocking the tube. The shortness of the neck conduces to the easy introduction of the cement. The plan of first placing a known weight of cement in the flask and then running in 50 cc. of liquid appears at first sight preferable to the method described above, but the complete displacement of the air entangled in the cement is less easily accomplished than when the cement is caused to shower down through the liquid. The first 14 cc. represents that portion of the displacement of the cement accommodated in the body of the flask which, as stated above, has a capacity of 64 cc. to the lowest graduation mark; the remainder of the displacement is registered on the stem. The temperature of the turpentine must be known, but need not be fixed at any standard point, and after the operation the volumenometer (which is stoppered to prevent evaporation) is brought to the same temperature by immersion in the same vessel of water as that previously used for the stock-bottle of turpentine. As all ordinary Portland cement has a specific gravity, such that the displacement of 50 grms. falls between 14 and 17 cc., this range of the graduations on the stem is ample. It is obvious that in dealing by means of this instrument with any material differing largely in specific gravity from 3, more or less than 50 grms. can be taken so as to bring its displacement within the range of the graduations on the stem. Seeing that in all cases the temperature before and after the displacement of the liquid by the cement must be identical, because of the high coefficient of expansion of turpentine and petroleum, it is evident that an apparatus of small total capacity, such as that just described, is convenient, as it can be immersed bodily in a beaker of water and brought to the proper temperature with ease and rapidity. In this, as in the forms of volumenometer previously described, the indications of the instrument are in no way dependent on alterations of the specific gravity of the liquid selected that may take place on keeping, so that a large supply of dry turpentine or petroleum can be prepared at one time and used to the last drop without further examination.

The deductions to be drawn from the specific gravity of a cement are various, and are modified by a knowledge of its other properties. It may be taken as a safe rule that the specific gravity of a true Portland cement of good quality, fresh from the stones, will be not less than 3.15. The same cement on exposure to air in a thin layer for a week may have decreased in specific gravity to 3.10, and further decrement is possible on continued exposure. The aeration to which the sample has been subjected must therefore always be taken into consideration in judging a cement from its specific gravity. It follows from this that the specific gravity of a cement will be found to decrease as the quantity of volatile constituents absorbed from the air (water and carbonic anhydride) increases. Indeed, experience enables the analyst to predict the specific gravity of a cement with fair accuracy from its analysis, provided the composition fall within ordinary limits. With cements of less regular composition than Portland cement a greater range of specific gravity naturally occurs. So-called natural cements, *i.e.*, hydraulic cements made by burning argillaceous limestone of approximately the same composition as slurry, come nearest to Portland cement in this respect, and are followed at some distance by Roman cements which have a specific gravity of 2.5–3.0. In cements of the puzzolana class, including slag cement, the specific gravity depends more on accidental circumstances than on the intrinsic quality of the material, and is therefore rarely of much importance.

*Time of Setting.*—The setting of hydraulic cement being a gradual process, methods for defining its period must be more or less arbitrary. At present the Vicat needle and its modifications still hold undisputed sway, though at least one ingenious apparatus has been devised for giving an autographic record of the setting process. Only two points need notice here. The first is that most cements are rendered slower setting by keeping, consequent on the hydration of the calcium aluminate, to the presence of which the initial setting is to be attributed, and therefore the setting time of a cement tested in this country and then abroad, after a lengthy voyage, will differ, being longer in the latter case. Want of recognition of this fact has often led to trade disputes. The second is that the temperature of the room in which the cement is exposed has a serious influence on the speed of setting. A higher temperature means more rapid setting. As no definite relation can be traced between the temperature and the time of setting, specifications in which stress is laid upon the time of setting falling within certain limits should state the temperature at which the test is to be made, and the cement tester should take steps to attain and maintain that temperature, by artificial means if needful.

*Strength in Tension and Compression.*—So much has been written about the testing of the mechanical strength of cement, and the information is in such accessible form for all interested in the subject, that it would be useless and wearisome to recapitulate what is a matter of common knowledge. We will confine ourselves to indicating what are the streams of tendency in this country at the present time. In the first place, the righteous condemnation of the demand—which demand is now on the wane—for an excessive tensile strength at short date, has carried some of its upholders to the opposite extreme, and led them to look with suspicion on cement merely because it is above the average in strength. It is surely unreasonable to condemn a material on this ground, always provided that its reliability be indisputable. (The means in use for deciding upon the safety of an hydraulic cement will be dealt with under a separate head.) Secondly, the substitution of compressive for tensile tests has made but little progress, and is unlikely to make much more. The latter method may be illogical, but is certainly convenient. In the third place, the use of sand in place of neat tests is growing daily, and will continue to grow as the demand for a more finely ground cement increases. In neat tests the full cementing power, as distinct from cohesive value of a cement, never comes into play, and a comparatively coarse sample may give tests as high as those afforded by one unusually fine. With sand, on the other hand, the property of surrounding, coating, and uniting inert particles (*i.e.*, the sand) is exercised, and the finer of two cements equal in other respects will give the better result. In view of the general increase in fineness of cement, it is not improbable that a sand test with a higher proportion of sand (1 of cement to 3 of sand being at present usual in this country) may be adopted with a corresponding advantage for finely-ground cements. Another useful innovation would be the insistence on mechanical tests of concrete made of the same sand and aggregate as that intended to be used for any given undertaking. The best cement may be rendered useless by admixture with bad sand and aggregate.

*Tests for Soundness of Cement.*—Owing to the fact that the completion of all the reactions initiated by contact of cement with water takes place only after the elapse of a considerable time—often extending to many months—the mechanical properties of ordinary test pieces when determined within a few days or weeks after the date of their preparation, are no certain criterion of the reliability of the cement. This circumstance has led to the device of special tests intended to meet the need of arriving at the same results in a short time as would eventually occur after the elapse of a long period.

The natural suggestion that any chemist would make, on being confronted with this requirement, is that the test pieces should be kept under conditions that would hasten the completion of the reactions occurring in them, and that an increase of temperature would be likely to effect this

purpose. This idea underlies all the varieties of "hot test" that have been proposed and practised from time to time. In its simplest form the "hot test" may consist in merely heating a pat of neat cement in an air bath to a moderate temperature (*e.g.*, 160° F.) and observing whether it buckles or develops any cracks, and whether it shows signs of weakness when wetted after heating. A distinct advance on this is achieved by exposing pats of neat cement to a warm damp atmosphere, or actually immersing them in warm water. Although it cannot be said with certainty that results are obtained by such tests identical with those that would be arrived at by efflux of time, yet it may be safely asserted that any thoroughly unsound cement will be detected and nearly all sound cements will be passed. It is not our purpose to discuss here the causes of unsoundness of cement, for such discussion would be foreign to the subject of this paper, but it may be mentioned that in nine cases out of ten a cement fails because it has been made from an imperfectly burnt clinker, and contains a certain amount of unsaturated base, which is conventionally known as "free lime." No one has yet succeeded in determining free caustic lime in cement, the problem being one of extreme analytical difficulty, but there is good reason to believe that unsaturated lime exists in badly burnt clinker, and, therefore, in the cement produced from it. Consequently the phrase is defensible on the score of convenience.

A system of hot testing which gives a quantitative expression of the unsoundness of a cement is that devised by Deval, and fully described in this Journal (1891, 255). From the results of a long series of experiments with various kinds of hydraulic cement, Deval established the fact that in most cases a sand briquette (1 : 3) kept in water at a

temperature of 176° F., 80° C., for two days has the same tensile strength as one kept in water at the ordinary temperature for seven days, while a similar relation holds good for briquettes kept in water at 176° F. for seven days and those kept at the ordinary temperature for 28 days. This is found to be generally true of normal hydraulic cements of good quality. In the case of an indifferent

cement the hot test pieces have a lower tensile strength than those exposed to the ordinary temperature, while those of an unsound cement crack and disintegrate.

At the date of the introduction of this method of testing we made a series of experiments on cement of various makes, the results of which are indicated in the table on preceding page.

The upshot of these experiments was that but few English cements made in the Thames and Medway district could be relied upon to stand the test unless previously aerated. The cause of this result is probably the difficulty of preventing underburnt clinker (of which a certain proportion occurs in most charges as drawn from the kiln) finding its way to the stones, and giving rise to the presence of some quantity of unsaturated base ("free lime") in the cement. When underburnt clinker is eliminated the test is most useful in discriminating between cement of normal composition and that containing unsaturated lime or other base. We have used it extensively in determining the quality of raw materials for cement making, and found it of great value. The following samples of cement were made in our laboratory:—

Analyses of some of the above samples are given in next column.

With regard to this series of tests it will be observed that a percentage of lime that would be considered excessive in cement manufactured on a large scale is no bar to perfect strength and soundness in one that has been burnt with the thoroughness possible in a laboratory trial. Samples 1 and 6 may be especially noticed. This circumstance goes

to show that uneven and defective burning is one of the chief causes of imperfection in commercial cement, and indicates in what direction improvement is chiefly to be expected.

For carrying out the Deval test, a bath of water kept at 80° C. = 176° F. is essential, as the operator is not justified in departing from the exact prescription of the originator of the test unless he be prepared to establish relations corresponding with those worked out by Deval between hot and cold tests, for such other temperature as he may select. For this reason all attempts to substitute temperatures more easily maintained, e.g., 100° C. = 212° F., for that adopted by Deval, cannot be usefully discussed while the data to support them are lacking. It being conceded that a temperature of 80° C. is essential to the proper execution of the Deval test, it remains to ascertain the most practicable method of maintaining this temperature with reasonable constancy. The use of an ordinary thermostat is not wholly satisfactory in a case of this kind. The hot bath to contain the briquettes is more a piece of testing-room plant than a laboratory apparatus, and its management is not necessarily in the hands of a chemist. Glass thermostats are therefore rather too delicate for the purpose in hand. For a large tank used in carrying out the Deval test, we first constructed an air thermostat of the usual design for this class of instrument, with a long copper tube

coiled in the bottom of the bath so as to give a good-sized expansion chamber, and a steel tube bent to form a U to contain the mercury column controlling the gas supply. This worked very fairly, but was somewhat troublesome to set up and adjust, owing to the opacity of its parts, a drawback always felt by a chemist when he has to abandon the use of glass as a structural material. It also possessed the disadvantage common to most thermostats, viz., inadequacy of controlling power when dealing with large fluctuations in the pressure of the gas supply (e.g., differences of as much as  $1\frac{1}{2}$  to 2 ins. of water). In fact, a thermostat to be perfectly reliable, needs a governor on the gas supply to remove the effect of large differences of pressure, and in fact to do the rough work of control.

Having regard to these facts and also to the need for a Deval apparatus capable of use on cement works where no gas is to be had, we designed the apparatus shown in Fig. 4.

Fig. 4.

about to be stated. The principle underlying the working of the apparatus is simple enough. The outer bath, which, as it is provided with a good condenser, can be kept boiling vigorously, constitutes a source of heat at a constant temperature,  $100^{\circ}\text{C}$ . The inner bath is separated from the outer by a constant distance, which offers a constant obstruction to the transmission of heat from the outer bath. The temperature of the inner bath is therefore always less than that of the outer bath by a constant number of degrees. The size of the separating space must be determined empirically. It is best made sufficiently great to ensure the temperature of the inner bath being somewhat lower (when the space is empty) than that ultimately to be obtained. The obstruction offered by the separating space is then gradually diminished by introducing into it successive small portions of any convenient substance in grain or powder, e.g. shot or sand. By a few trials a point is reached when the obstruction to the transmission of heat from the outer to the inner bath is so adjusted that when the former is at  $100^{\circ}\text{C}$ , the latter is at  $80^{\circ}\text{C}$ . It is obvious that fluctuations of the gas supply, provided that it be always large enough to keep the outer bath boiling, have no effect on the temperature of the outer bath, and therefore are equally without effect on that of the inner bath. The only change of external condition likely to effect the temperature of the inner bath to an appreciable extent, is that of the temperature of the room in which the apparatus is placed. When the air temperature rises, loss of heat from the pyramidal cover, which is the only portion exposed to the atmosphere, naturally diminishes, while the supply of heat from the steadily boiling bath is maintained at its former rate; consequently the temperature of the inner bath rises slightly. The converse is true on a fall in the temperature of the air taking place. Experience has shown that the fluctuations due to this cause are not large in an ordinary laboratory atmosphere, of which the temperature does not vary greatly; they might, however, become considerable if the bath were used in an unprotected shed or other slight building. The apparatus in the form shown is quite independent of any particular method of heating. It can be used with a paraffin lamp as well as with a gas burner, the sole condition being that the source of heat shall always be sufficient to keep the water boiling briskly in the outer bath.

We have dwelt at some length on the principle employed in this apparatus because it is, as far as we know, one that may be applied for many purposes through a considerable range of temperature, the essential features being (1) a source of heat of constant temperature, such as is obtained by the use of a liquid for the outer bath having a definite boiling point; (2) a space between the outer and inner bath offering a constant resistance to the transmission of heat; and (3) a fairly even air temperature, so that the loss by radiation (which may be made small by minimising the area of the radiating surface) may not fluctuate largely.

Many hot tests, other than that due to Deval, have been devised, but the only example that need be quoted here is that known as Erdmenger's high pressure test. It consists essentially in exposing briquettes to the temperature obtained in a closed boiler carrying a pressure varying from 10 to 40 atmospheres. It is claimed that sound cement rapidly attains the strength at which it ultimately, after a period of weeks or months, arrives under normal conditions, and that an unsound cement—especially one containing an excess of magnesia—acquires a low tensile strength or disintegrates, according to its degree of faultiness, and the temperature to which it has been exposed. The establishment of quantitative relations as definite as those existing in the case of the Deval test does not appear to have been effected with the Erdmenger test. It is not quite apparent what purpose is served by using the high temperatures and consequent high pressures that distinguish the Erdmenger test from others of its kind. Indeed the temperature, which at 20 atmospheres is  $212^{\circ}\text{C}$ . =  $415^{\circ}\text{F}$ ., may be so high as to cause the dissociation of the products of the hydration of the cement to which its character as a cement is due. Such dissociation may occur even in an atmosphere consisting of one of the products of dissociation, i.e., water, an inference borne out by the statement that

A is a rectangular copper water-bath completely closed save for a small hole B, to which a condenser can be attached. This condenser may be a straight metal tube, jacketed with water like a Liebig condenser, or, if space permit, a piece of lead or "compo" pipe, 10 feet long or so, passing out of the room containing the bath and going up the outside wall to a neighbouring chimney. An air condenser of this kind is cheap, convenient, and, if long enough, quite effective even in hot weather. The tube must be vertical, or have at least a sharp rise, and be free from any kink or obstruction, or the return flow of the condensed water will be impeded. The top of the water-bath A is not flat, but has a rectangular depression or well into which the hot bath C, to be maintained at the required temperature, fits, clearing the walls of the well, and supported by a flange on the top of the bath A. A pyramidal cover D is provided for the bath C, and, if fitting well, suffices to condense such water vapour as may be given off at  $80^{\circ}\text{C}$ . The space between the inner and outer bath is either empty or filled partially or entirely with sand or shot, for a reason

long exposure at high temperatures in the Erdmenger apparatus is capable of causing the deterioration of cement of admittedly good quality. With regard to the detection of magnesia, actual analysis must be in every case preferable to any mechanical method of testing, however drastic and ingenious, and as the permissible limit for magnesia is now pretty well defined, no exception to the exclusive use of analysis for this purpose can well be taken. A highly practical objection to the Erdmenger test may also be urged, viz., that it is doubtful whether good Portland cement as made in this country can be relied upon to pass it; it is generally conceded that the Deval test errs, if anything, on the side of severity, and until a stage of manufacture has been reached capable of producing cement which can pass the milder test, it is useless imposing a more exacting criterion.

**Analysis.**—The actual analysis of hydraulic cements is not a difficult matter, and to detail such methods of separation and the precautions in using them adopted by us would not be of sufficient interest to compensate for the space which the description would occupy. It is sufficient to point out a few of the pitfalls that beset the tyro in matters of this kind.

Thus it is futile to attempt to determine "free lime" by any method which does not take into account the fact that the cementitious compounds proper to hydraulic cements are themselves decomposed by water, and therefore yield an alkaline extract with any aqueous liquid. As far as we are aware no reliable method of determining "free lime" in an hydraulic cement has ever been published. There is good reason to believe that an extremely small quantity of "free lime" (1 per cent. or less) is present in Portland cement of good quality, and analyses showing anything in excess of this should not be accepted without close scrutiny. The separation of the silica—as distinct from the insoluble silicates, sand, &c., which amount to not more than 1.5 per cent. in an ordinary Portland cement—into "soluble" and "insoluble" is a purely arbitrary distinction turning merely on the particular conditions of working adopted by the analyst. The whole of the silica separated by the decomposition of the cementitious silicates by means of hydrochloric acid is "soluble," and no distinction in function between different portions of it has yet been successfully drawn. The return of "moisture," which is sometimes set down in cement analyses, is an error too obvious to need comment. It would be nearly as rational to return "moisture" in a sample of quicklime. In the analysis of cement, as in that of most siliceous and earthy materials, especial attention must be bestowed upon reagents, filter-papers, and vessels, lest small quantities of silica, alumina, and lime creep in during the course of analysis and cause an apparent creation of matter when the analysis comes to be added up. A similar surplus sometimes arises from the insufficient ignition of precipitates that are not easily brought to a constant weight, e.g.,  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{CaO}$ . For such substances we invariably use a gas-muffle. Finally, it must be remembered that the best possible analysis of cement is not proximate, the separation of the actual compounds forming the cement, to which its properties are due, being still beyond the range of analysis. A double measure of caution must therefore be used in arriving at a judgment from data that are necessarily not exhaustive.

In conclusion it may be said that neither by the analysis nor mechanical testing of cement singly can its quality be gauged with complete certainty. It is imperative that both chemical and mechanical data should be available before a positive pronouncement can be made. Although experience allows a valid opinion to be passed even when such complete data are not forthcoming, yet the removal of the opinion into the ranks of ascertained facts can only be accomplished by determining both the composition of a cement and its leading physical properties. When both have been ascertained, the suitability and safety of a cement for any given purpose can be accurately adjudged.

#### DISCUSSION.

Mr. W. HARRY STANGER said that, until his association with Mr. Blount, his practice was entirely confined to the testing

of cements by mechanical methods. The results were, never, in his opinion, absolutely reliable; with high unquestionably in trained and experienced hands, they were sufficiently so to ensure a just appreciation of the merits of the sample under test. The main difficulties in the way were the various shapes of "standard" bushed measures, the means used for filling the measures, the grading and mixing of the cement, and the speed of application of the load. Bushed measures (all Imperial stamped standard) varied in shape from shallow tubs 8 in. deep by 19 in. diameter to cylinders 15 in. deep by 13 in. diameter. Each had a bushed by measure, but as the weight also of the measured material was wanted, the shape of the measure itself was an important factor when dealing with so compressible an article as Portland cement. The measure and hopper exhibited were chosen and designed by Mr. William Mathews to ensure in all cases equal treatment, and this apparatus had now come into very general use. The mixing of the cement with water was an operation requiring "knack" and experience which were not always available, consequently the excellent device designed by Mr. Rajja was largely used. The automatic apparatus for applying the load to the briquettes was also the invention of Mr. Mathews, and by its means the accuracy of cement-testing machines had been immensely improved. Sufficient attention had never been given to the construction of the sieves. He had tested many sieves, and he could not remember a single case in which the number of holes stamped upon it by the maker agreed with the number per square inch it actually possessed. The wires used varied considerably, and he knew of cases in which sieves alleged to be "40" "40," *i.e.*, 1,600 holes to the square inch, neither possessed that number, but actually had holes smaller than sieves stamped "50" "50," *i.e.*, 2,500 per square inch. He mentioned the above facts as his instruction for calling in the assistance of the chemist. By the improvements in the mechanical apparatus already mentioned, much had been done, and he was glad to find that engineers were beginning to grasp the fact that the manufacture of hydraulic cements was really a chemical process, that precision and accuracy in the testing of the product were essential, and that as it was necessary to know a great deal about the material which mechanical testing, however careful, could not suffice to determine. The services of the chemist were therefore indispensable. If all users of cement would follow in the lines of those thoughtful engineers who now called in the chemist's aid, we should hear of fewer failures and cease to be agitated by periodical scares.

Mr. W. F. RENN said this subject was by no means a new one, and had been pretty well thrashed out, but still, even this paper did not contain some of that which was newest in this particular branch. With regard to the coarse particles left on the sieve used for testing cement, it had been known for a great many years that those were comparatively useless. In fact, Michaelis, in his book in 1869, said that they were inert and as useless as sand. He had stated practically the same thing about the same time himself. The question whether this fineness could be tested by means of a sieve was very important. Recent experiments in Germany tended to show that everything that went through the finest sieve was not really what you could call a cementing agent; that even through the finest silk gauze used in flour mills cement passed which was extremely slow in attaining its ultimate strength. That had been further separated by means of a current of air, and there was a very ingenious apparatus used in Germany for that purpose. They tested not only with a current of air but also adopted the method of elutriation, using a liquid not acted on by the cement. He would warn anyone who had not great experience against using turpentine for this purpose. He had frequently used it himself and found that it was a liquid of very variable specific gravity, generally containing a good deal of moisture, and it had a considerable action on the lime which was undoubtedly present in the Portland cement, and which, if not absolutely free, would react with anything with which it came in contact. The test by the weight per bushel was originally introduced by Mr. Grant, assistant engineer of the Metro-

politan Board of Works, who, he believed, took it from a French engineer. It was said in the paper that it doubtless arose from the fact that it was a convenient method of comparing the weight with the volume and was therefore a convenience to engineers in prescribing the requisite quantities. But that was not the case. One reason why it was introduced was to distinguish Portland from Roman cement. The first makers of Portland cement were not quite sure of the quality, and he knew on very good authority that they frequently mixed a little Roman cement with it to bring it up to the required strength. Of course that was perfectly ridiculous now, but in those early days it was sometimes a toss up whether a kiln was going to be good or bad. Engineers then thought it was sometimes necessary to distinguish Portland from Roman, and when mixed it was very difficult; but this was a means of doing so. Another reason which prevailed then—though it might not now—was light-burning. There was an incentive to light-burning, and although one could discover whether cement was light by its tensile strength, no doubt a good deal of light cement did come into the market at first. The weight test as a test—and there was an apparatus shown for carrying it out—was absolutely valueless, and if he had been writing on the subject he should have said weight per bushel was an old test which was now useless. A coarser-grained cement weighed heavily, and the same cement finely ground, and hence more valuable, weighed lighter. In the present state of knowledge, if such a test were specified at all, it ought to be that cement should not weigh more than so many pounds per bushel, but no engineer thought of doing that. The difference in the weight of a coarse and fine cement had been stated by a well-known French engineer to amount to as much as 20 per cent. on some samples. That is to say, you could take a cement which weighed so many pounds per bushel and grind it until it weighed 20 per cent. less per bushel. With a margin of error like that, it was perfectly impossible to attach any importance to the figures. As Mr. Blount had said, the specific gravity of all cement was about the same; there was only a comparatively small range of difference. Much importance was attached to this test by Fresenius, who regarded it as one of the best means of distinguishing between cement adulterated with slag and true Portland cement; but this test had since been abandoned, as it was found useless for practical purposes. It was very interesting scientifically, and the little apparatus shown would no doubt give the specific gravity with a minimum of trouble. He never took the specific gravity unless requested, though he had tested and made many hundreds of thousands of tons of cement. He agreed with the authors with regard to the importance of sand testing, and the time of setting was also extremely interesting from a theoretical point of view. From a practical point of view, however, it was absolutely necessary to get a simple test which could be applied to all cements by almost anybody in the habit of conducting such operations. If the ingenious apparatus shown on the table were required for ascertaining the time of setting, he feared it would add considerably to the cost of the installation of a laboratory at a cement works and less cement would be tested where it ought to be—by the makers. Testing with sand was certainly the best method known of ascertaining that which was the chief object of a cement—its cementitious value. The difficulty here arose that you introduced another substance which was in itself variable. No two sands were alike. In Germany they got over that difficulty in the usual way, by standardising it. There was a normal sand, a normal testing station, and a normal price, but we had not arrived at that stage here; there was no sand which had been agreed upon by engineers or any public body which could be taken as a standard sand. It was not enough to take sand of a definite size, or even pure quartz sand of a definite size, because much depended on the shape of the grains, and as there was no uniform sand there was a great difficulty about this test. Mr. Grant, who had done so much for the testing of cement, tried a great number of experiments and found nothing so uniform as quartz sand, and he used sand from a certain place and recommended it to all his friends; but you could not say there was any standard sand. With regard to the

heat test which was ascribed to Deval, it was not his originally. It was first used by Michaelis and then by Edmenger. He had worked at it for the last 15 years. He tried it to ascertain the effect of magnesia on Portland cement, which was a subject which had been very much talked about lately, and he found that where he used a high temperature, superheated steam, he could detect the presence of magnesia. It was not generally adopted in Germany by experts, and in France it had been rejected for the following reason:—Several factories, whose cement was undoubtedly excellent, and which was used largely by the Government and found to be thoroughly excellent, could turn out no cement which would stand this test. The cement could not be wrong, as it had been used for a number of years satisfactorily, and therefore the heat test must contain some latent defect, probably because in a short time the cement had to exert an action which ought to have been distributed over a much longer period.

Mr. BURNAYS said he had lately had a good deal of experience in using cement, and had to thank Mr. Blount for making many special tests for him. He was a little frightened at some statements in the paper, because he found most of the tests hitherto recommended for use more or less run down by the very gentlemen who had either invented or improved upon them. Engineers were working as far as they could in accordance with what they had learned from specialists, but one after another those tests which had frequently been considered good were now deprecated and something new was presented for their acceptance. In their ordinary practice they ascertained the weight per bushel, the tensile strength, and the fineness, with some precautions, and found that the result was very uncertain. Sometimes they got a cement which bore the weight test well; at other times, from the same makers and made, according to their statement, in exactly the same way, they had a cement which weighed very differently, and when they came to try the cement by sifting it and taking the amount of the residue they found it very different from the previous sample. Then they made tests with briquettes, breaking them with the machine and obtaining at times very extraordinary values. Sometimes from one sample of cement they got briquettes which would after seven days break at perhaps 250 lb. per square inch; another briquette from the same set would break at 500 or 550 lb., and they had not the slightest notion how the difference could arise. But the most curious thing of all was that, in spite of all these varying results, all the cements they had used were of excellent quality, whether the test had turned out well or not. They were all cements which came from a good firm, were made to comply with a given specification, and they made first-class foundations, as hard as steel, and as lasting, he believed, as the earth itself.

Mr. MATTHEWS said he had been a user of cement during the last 25 years, and his experience did not in many respects coincide with the remarks of the first speaker. First, with regard to the hopper and bushel measure, he found such an apparatus extremely useful in determining the weight of cement. Many years ago he used a cement which, when sifted through a 40 × 40 mesh sieve with a 10 per cent. core, gave an average weight of 120 lb. per bushel. Now cement was ground to give 10 per cent. core on a 50-mesh sieve, thereby reducing the weight per bushel to 116 lb. If they employed a 76-mesh sieve they had to still further reduce the weight to 110 lb. If you expected to get the same weight per bushel with a fine as with a coarsely ground cement you would be altogether disappointed. He had used the bushel and hopper for many years and found that by careful handling it gave results as to weight, with cement of the same fineness, within 2 lb. per bushel. When an inspector was sent to a works to examine a parcel of cement he would sometimes be shown a heap of 400 or 500 tons. Instead of getting two or three pinches to try the specific gravity he would take a bushel from different parts of the heap, and by that means get a fair idea of the average weight of the cement, thus showing whether the clinker from which the material had been ground was properly burnt. The main object of the weight test was

to show, before proceeding with further tests, whether the underburnt or yellow clinker, which was, he took it, the dangerous element in cement, had been picked out and cast aside, and that only well-burnt clinker, which gave a good sound cement, had been ground. He agreed with the authors of the paper generally as to the desirability of fine grinding. They were all tending in that direction. A very fine sieve was, however, a delicate thing. When the authors referred to a sieve of 160  $\times$  160 meshes to the inch it must be evident that the wire in it would be extremely fine, and the slightest damage to the sieve would upset the results. Therefore he looked in some other direction, possibly in that at which the authors hinted in their paper—towards an improvement in the determination of the amount of the core, or those particles in the cement which were incapable of setting. It was a matter of great importance that the extent to which those particles prevailed should be determined. He did not think they always arrived by the sieve at what that proportion was in extremely fine cements, and some other process would no doubt be devised to determine this point. He had tried blowing air through cement and other means, with the idea of determining the amount of the core, but found difficulties arose. He quite agreed that the sand test was a valuable one, but for engineers as a guide in accepting cement it was not practically of much use. They could not expect makers to keep large quantities of cement under trial and unaccepted for 28 days, whilst sand tests were being made. The sand test, as a check to the used by engineers after the delivery of the cement, was useful, but was not capable of practicable application generally as a guide upon which to accept or reject cement. Aeration of cement before use was of the utmost importance as promoting soundness of work. He had used cement which had been in a dry shed near the sea for 10 months, and the effect of age and aeration was to reduce the weight per bushel to the extent of 12 lb. On instituting tests to ascertain whether or not the strength had deteriorated, it was found that, although the two days' test was slightly less, the seven days' test was fully maintained. As a matter of fact they kept that cement for pointing, and the best work on the job, as they found it was the soundest and most satisfactory material. He had recently made experiments to determine what was the effect of turning over cement on its bulk. He found that six turnings, allowing the cement to stand a short time between each, increased the bulk 6.25 per cent.; 12 turnings, 7.80; 18 turnings, a similar increase; thus showing that after about 12 turnings there was no increase of bulk. He believed that the increase of bulk consequent on three or four turnings was a positive gain to a contractor, because he bought his cement by weight and sold it by measure, so that the increase in the bulk would pay for the cost of turning. He hoped engineers would endeavour to induce contractors to adopt this practice, seeing the value of aeration in securing sound work. With regard to analysis, he held such an investigation of great importance, as determining the percentage of lime and other constituents of the cement. Where the soundness and permanence of structures so largely depended upon the satisfactory character of the cement, as is generally the case in these days of extensive employment of concrete, every precaution should be adopted in carrying out the tests and in placing the same in the hands of experienced men.

Mr. HUGHES asked Mr. Blount to explain more fully the analyses on the diagram, and to state which was the better.

Mr. BLOUNT, in reply to Mr. Hughes, said that the cement marked No. 6 was undoubtedly the better of the two, in spite of its high content of lime, because coarse sand had been eliminated from the raw materials by washing, and the clinker had been thoroughly burnt. With regard to what Mr. Reid had said, he (Mr. Blount) thought that on reading the paper Mr. Reid would see that there was substantial agreement on many points between them. The fact that coarse particles in cement had little cementitious value had long been known by the few, but it was only now becoming generally recognised, and for that reason particular stress had been laid upon it in the paper. He was interested in Mr. Reid's information concerning the origin of the weight per bushel test, and thought the explanation probable

enough. Whatever its origin, however, it had come into general use, and had to be taken into account in any paper dealing with the testing of cement. It was somewhat embarrassing to find that Mr. Reid viewed him as a defender of the weight per bushel test, when as a matter of fact his whole opinion and course of argument were for its replacement (as far as practicable) by the determination of specific gravity. With regard to what had been said as to the abandonment of the determination of the specific gravity, he could only regret that those called upon to pronounce upon the quality of cement, should deprive themselves of what, in his opinion, was a valuable criterion. It neither the weight per bushel nor the specific gravity was worth determining, the onus of devising a better test plainly rested on the critics of these methods of testing. A normal sand would doubtless be a convenience, and such a sand was already used by Mr. Stanger and himself. There was no ground for supposing that Deval claimed to be the originator of the hot test; the contrary was clear from what had been said in the paper. What constituted the cardinal merit of the Deval test was that it was exact and quantitative, its forerunners being merely qualitative, and based, moreover, on less cogent and complete experimental data. Personally he knew that, especially in pronouncing upon the quality of new raw materials for cement making, it was invaluable. The detection of magnesia by any method of mechanical testing was a poor substitute for the precision of its analytical determination.

The continual displacement of old tests by new, and the apparent contradictions involved, mentioned by Mr. Bernays, were a necessary incident of progress.

In reply to Mr. Matthews' criticism, based on the use of a small quantity of cement for the determination of specific gravity in place of the hundredweight needed for the weight per bushel test, he would say that it was an easy matter and one of everyday experience to obtain a pound or so of material that should be absolutely representative of a thousand tons or more. Sampling, properly conducted, would remove the risk of the portion taken for the specific gravity not fairly representing the bulk. Given a representative sample, the error in the determination of specific gravity would be less than 0.2 per cent., whereas that of the weight per bushel was, as Mr. Matthews had mentioned, about 2.0 per cent.—10 times the former value. He was much interested in what had been said anent the sizing of cement by other means than sieves, and was gratified to find that Mr. Matthews agreed with him in believing that a practicable method of elutriation—whether by a liquid or a gas—might be worked out, and a standard process arrived at.

Meeting held Monday, May 21st, 1894.

MR. WILLIAM THORP IN THE CHAIR.

#### A JAPANESE PSEUDO-SPEISE (SHIROMÉ), AND ITS RELATION TO THE PURITY OF JAPANESE COPPER AND THE PRESENCE OF ARSENIC IN JAPANESE BRONZE.

BY W. GOWLAND, A.R.S.M., F.R.S., F.I.C., LATE OF THE IMPERIAL JAPANESE MINT.

IS the separation of silver from copper by lixiviation with lead by the Japanese process, known as the "namban fuki" method, an alloy of copper, arsenic, lead, and antimony, called "shiromé," is obtained as a by-product, in larger or smaller quantities, according to the nature of the copper treated.

As this substance is unique in composition among metallurgical products, as, besides, it forms an important

constituent of some Japanese bronzes and allied alloys and has not hitherto been analysed or described, the following notes on its occurrence, composition, and uses will, I hope, be of interest to the members of our Society.

The process, too, in which it is produced will not be of less interest, as it possesses several important features and exhibits some curious relations or affinities of the metals copper, lead, arsenic, antimony and bismuth, under conditions which are not found in ordinary metallurgical operations. Affinities which have played a prominent part in the separation of the three latter metals from Japanese copper.

I propose now, with your permission, first, to describe the process in which the shiromé is a by-product, and its effects on the copper treated by it, and subsequently to consider the by-product itself.

The process of liquating copper with lead for the separation of silver is called, as I have stated above, "namban fuki," which signifies "melting after the style of the southern barbarians," the method having been introduced into Japan by the Portuguese. Since the date of its introduction, about the latter half of the 16th century, it has been continuously employed in the treatment of all copper containing sufficient silver to pay for its extraction.

As most of the copper ores of the country are more or less argentiferous the process has been and is still in extensive use, and very large quantities of silver have been extracted by means of it. Some gold also has been obtained, but only a part of that present in the metal treated can be liquated out with lead, a considerable proportion being always retained in the copper.

This process was not, however, introduced by the Portuguese in its present form. What they introduced was the old German method, known as "Das Saigern," only the principles of which have been followed by Japanese metallurgists, who, with these principles as a basis, developed the furnace, appliances, and method of liquation which are now in use and which are essentially Japanese.

Great credit is due to these metallurgists, especially to those of the early days, for the ingenuity they have exhibited in their radical alterations of the European method, for by these alterations they have not only made the process suitable for the work of the smallest mine, but have achieved results with it on all scales far surpassing in economy and in completeness of separation of the respective metals anything that had been accomplished by it in its original form.

Thus, for example, in the Japanese process less lead is required, a lead richer in silver is obtained, less lead and silver are left in the copper, and as small a quantity as 80 lbs. of copper can be treated at a time.

Copper suitable for liquation:—

The amount of silver in the copper which is necessary to make the liquation process a profitable one varies in different parts of the country.

In Tokio, 0.077 per cent. silver (25 ozs. 3 dwts. 1 gr. per ton) is said barely to pay the costs of the operation, but in other localities, where charcoal and labour are cheaper, this proportion of silver would be remunerative.

Generally speaking, in all districts when the copper contains 0.092 per cent. silver (30 ozs. 1 dwt. 2 grs. per ton) or more it is subjected to this process.

The following analyses (No. 1) show the proportions of silver contained in typical specimens of copper from different localities.

Two specimens of copper from Korea are included in this table as they represent the most highly argentiferous crude copper I have met with in the East. The occurrence of such large percentages of silver in these specimens leads me to direct the attention of miners and metallurgists who may proceed to that country to the copper ores as sources of silver, as hitherto prospectors have confined their search for the metal to outcrops of galena and silver ores proper, and have not had the success which their energy deserved. The large amount of gold in the copper from Towata is worthy of note. About five tons of the sample containing 25.51 oz. per ton were imported into the imperial mint as crude copper, the importer being ignorant of the presence of gold in it until he received the assay report.

The operations of the Japanese liquation process are divided into two stages, each being conducted in a different furnace, viz.:—

A. Preparation of an alloy or mixture of copper and lead.

B. Separation of the lead (and with it the silver) from the mixed metals.

When, however, the crude copper already contains sufficient lead, stage A is omitted and it is submitted at once to the operations of stage B.

Several mines in the province of Hida, where the metal is obtained by smelting ores rich in galena, yield copper of this description, in which the amount of lead, as will be seen from the following analysis, occasionally reaches 39 per cent.

## No. 2.

## CRUDE COPPER CONTAINING EXCESS OF LEAD (PROVINCE OF HIDA).

	Per Cent.

Antimony.....	Nil.
Sulphur.....	1.64
Silver.....	0.185
Gold.....	Trace.
	100.055

This is exceptional, and generally in most districts the addition of lead is required.

Stage A.—Preparation of the mixture of lead and copper:—

The proportion of lead to be mixed with the copper varies at different mines and smelting works, ranging from 1 part of lead to 55 parts of copper at Ani (prov. of Ugo) to 1 part of lead to 3 parts of copper at Omodani (prov. of Echizen), the general ratio being about 1.4.

Both lead rich and poor in silver are used, the former being preferred when it can be procured, as more silver can be obtained from it than the old Japanese methods of assaying indicate, and the final cupellation is hastened.

The amounts of silver usually present in these two kinds of lead are as follows:—

Fig. A.

MELTING FURNACE.

The furnace used is the typical Japanese smelting furnace shown in Fig. A. It consists simply of a rudely hemispherical hole about 16 in. diam. and 15 in. deep in a specially prepared portion of the ground of the smelting room, lined with a brusque of refractory clay and charcoal, and to which a blast is supplied through a clay twyer from the ordinary double-acting hand bellows in general use in China and Japan, which is placed behind the furnace.

Ignited charcoal is placed at the bottom of the cavity, which is then nearly filled up with fresh charcoal. Upon this the copper, which is in irregularly-shaped lumps, is placed, and more charcoal is heaped up over it.

The bellows are then started, more copper and fuel are added from time to time until the whole of the charge has been put in, and the blast is continued until all the copper has completely melted. The fire is then raked off, the metal skimmed, and the lead added and mixed thoroughly with the copper.

The alloy is then removed from the furnace by means of a curious tool consisting of a rudely spherical-shaped iron head about 4 in. or more in diam. attached to a long handle. This is dipped into the molten alloy, lifted out, and the adhering crust of metal knocked off and thrown into water. The tool is then cooled with water and another crust taken out, and this is continued until the furnace is emptied of its contents. This part of the operation is graphically shown in the Japanese drawing, Fig. A A. Six or seven charges, each of about 250—300 pounds of copper, are worked per day with a consumption of 20 per cent. of charcoal.

Fig. A A.

In a large copper refinery in Tokyo, erected after my designs, the copper is melted in charges of three or four tons, and is ladled or run out in quantities of half a ton at a time into a large casting ladle in which the lead is mixed with it. The alloy is then cast in iron moulds into flat plates with intersecting furrows, so that it can be easily broken up when cold.

The former method is, however, that in general use.

The copper-lead alloy is now taken to the liquation department, where the second part of the process, stage B, is conducted.

Stage B.—Separation of the lead from the copper-lead alloy.

The operations of this stage are carried on in a furnace of simple but ingenious construction.

A vertical section showing its general form, the arrangement of the twyer, and the curious fore-hearth is given in Fig. B.

Fig. B.

LIQUATION FURNACE.

SECTION ON A B (ENLARGED).

Its exterior, as well as that of the fore-hearth, usually consists of flat stones set on edge, but in the mint and some modern refineries these parts are built of brickwork.

(In Dr. Percy's Metallurgy—Silver and Gold—Part I., p. 341, a drawing is given by Mr. Tookey of the brick furnace used in the mint in 1871.)

The interior is a circular cavity about 18 inches in diameter and 13 inches deep, with clay sides slightly converging towards the bottom, which slopes downwards towards the front side.

From the front side the fore-hearth projects in the form of a shallow trough in a line with the bottom and inclined at about the same angle. Below the end of the trough there is a shallow circular hole in the ground for receiving the liquated lead.

The interior of the furnace and of the fore-hearth is lined with the usual brasque of clay and charcoal.

The front side is open, but is partially closed during working with a fire-clay tile.

The top is covered with a clay slab excepting a small opening which is used for the addition of fuel, and is also covered during working with a movable tile.

The blast pipe is usually of clay, sometimes of iron, and terminates in a clay nozzle or twyer which passes through the cover of the furnace. The twyer is bent sharply at an angle, the correct inclination of which is considered to be of great importance, its object being to direct the blast downwards and towards the middle of the back wall.

The furnace is placed under a hood for carrying off the fumes.

The charge of alloy weighing from 100—160 lbs. is placed on the bottom of the furnace, the larger pieces below, then a little charcoal, and then the smaller pieces. The front tile is now fixed in position, and the furnace almost filled with charcoal, the covering slab luted on, and the twyer adjusted.

Glowing embers are now put in, the charging opening is closed, and the bellows started.

The furnaceman then takes up his position, squatting on the ground in front of the fore-hearth.

Great skill is required in regulating the force of the blast, so that too high a temperature may not be produced, as the alloy must not be melted but merely brought to a pasty condition.

When it has reached this state it partly protrudes through the opening in the front on to the upper part of the trough forming the fore-hearth, and is there kept hot by the flame—which issues continually from this opening—passing over it.

The mass—a copper sponge saturated with lead—is now patted and squeezed by the workman with a tool consisting of a small block of wood about 5 or 6 ins. long and 3 ins. in diameter fixed on a hooked iron rod attached to a wooden handle, the lead trickling from it being collected in the hole in the floor (Fig. C.). As it becomes cool and lead ceases to exude, it is pushed back towards the hotter part of the furnace with a small iron rabble, and when sufficiently pasty it is again patted as before.

When the lead ceases altogether to flow from it the temperature is raised and the pasty mass is raked down the spout with further patting and allowed to solidify there.

The average duration of the operation is about 2½ hours, and usually three to four charges are worked per day, with a consumption of from 40 to 50 per cent. of charcoal.

The products of this liquation process are: copper containing little silver, argentiferous lead, and shiromé.

The specimen on the table is a sample of the copper in the form in which it is taken from the fore-hearth. Its composition is represented by the following analysis:—

No. 4.

Nickel.....	Trace.
Insoluble sandy residue.....	0.06
	99.831

Sometimes when the process has been hastily or unskillfully conducted the amount of lead retained by the copper exceeds that in this specimen, but the greatest amount I have found has been 0.97 per cent.

The lead which has collected in the cavity in the floor contains varying quantities of silver according to the amount present in the copper and in the original lead used for the liquation.

Rarely less than 0.25 per cent. (81.66 oz. per ton), frequently 1.3 per cent. (424.66 oz. per ton), and occasionally as much as 2.2 per cent. (718.66 oz. per ton), is present

Fig. 1.

It also contains the whole of the bismuth, a little of the arsenic and antimony which may have been present in the copper, and small quantities of copper.

Usually only about 80—90 per cent. of the weight of the lead added to the copper is obtained, the remainder being lost, part being retained in the copper, shiromé, and slag, and part being volatilised.

The lead is sent to the cupellation department, where it is first submitted to an oxidising-melting process on a hearth of wood ashes and clay, and then is cupelled on a similar hearth of smaller dimensions, a cake of silver containing a little gold being obtained (see specimen).

The shiromé accumulates on the outside of the spongy mass of copper in the fore-hearth in irregularly shaped semi-fused lumps, and is removed by the furnaceman from time to time during the liquation.

The amount yielded by any operation varies generally from 1—2 per cent. of the weight of the copper treated, but is entirely dependent on the purity of the copper; if this contains only traces of arsenic and antimony no shiromé is formed; if, on the other hand, much of these are present the proportion may greatly exceed 2 per cent.

When sufficient shiromé has accumulated in the liquation department it is twice treated by liquation with lead for the separation of as much as possible of the silver which it contains, but in spite of this treatment a considerable

amount of silver is always retained in it owing to the arsenic, which is one of its essential constituents.

*Note.*—The word shiromé (meaning "white solder"), the name of this substance, is unfortunately also used to designate antimony, the Japanese not having had any specially distinctive name for this metal excepting Iyo-shiromé or shiromé from Iyo (Iyo being the province in which the chief antimony mines were situated) until recently, when "anchimoni" was adopted from the English word. Frequently "Iyo" was omitted and only shiromé written.

The term is also applied to ordinary tin and lead solder. I think it necessary to mention these three uses of the name, as they have led to much confusion in Japanese metallurgical books, and especially in translations from them. Thus a careful and learned writer has conveyed a completely wrong impression of the composition of some Japanese alloys by translating shiromé as antimony when this copper-arsenic-lead-antimony alloy is meant.

Shiromé as it is obtained after liquation with lead is in rough irregular shaped, somewhat vesicular lumps. When melted and cast into ingots it is of a very dark bluish-grey colour. It is harder than lead, rather brittle, and can be reduced to a coarse powder by careful hammering in a steel mortar. Its fracture is dull, coarse grained, and free from crystalline structure.

The following complete analysis No. I. represents a sample taken directly from a liquation furnace at the smelting works of the Onodani mine (prov. of Echizen), which, as we shall see later, are noted for the purity of the copper they produce.

Nos. II and III are partial analysis of specimens from other districts, that from Iyo, No. II., having been liquated with lead for the separation of as much silver as possible.

The two determinations of lead and arsenic respectively were made in different portions of the specimen I., and they show that contrary to what might be expected it is tolerably homogeneous in composition. Its characteristic features, as will be seen from these analyses, are the presence of arsenic in considerable proportions, of antimony, of lead, and a large percentage of copper. In the specimen No. I. the occurrence of the two former metals in such large amounts is specially noteworthy, as it demonstrates that without treatment by the liquation process, by which this shiromé was obtained, the Onodani copper would be seriously contaminated with both, and would be noted rather for its impurities than for its purity.

I desire here to record the deep obligations I am under to my friend Prof. Roberts-Austen for having kindly placed the resources of the Metallurgical Research Laboratory of the Royal School of Mines at my disposal, so that I was able to make there not only the analyses of shiromé, but also to complete others which I had left unfinished in Japan.

After a very careful search I have failed to find any record of a metallurgical product approximating to shiromé in composition. A substance somewhat analogous to it in its mode of production is the Saigerdorner of the old German liquation process, but this, as will be seen from the accompanying analysis, differs entirely from it in composition.

\*Saigerdorner (E. von Szamit):—

Copper.....	11.36
Lead.....	79.68
Antimony.....	7.30
Silver.....	213.045
Gold.....	5000.065
	99.123510

It is impossible to assign any definite chemical formula to this complex substance shiromé, owing to its non-occurrence in a crystalline form, to the total absence of any crystals disseminated in its mass, and to its variability

in composition at different works. It may, however, be regarded as an arseno-antimonide of copper and lead, in which an excess of copper and lead is held in solution, *lev.* as a pseudo-speise. The various copper-lead so called speises, when they are the products of metallurgical operations, although differing from it in the relative proportions of their constituents, appear always to have this constitution, the amounts of arsenic and antimony present being less than sufficient for combination with the copper and lead. In this respect they are distinct from the true arsenical speises containing nickel and cobalt, in which the arsenic is frequently combined with these metals in definite atomic proportions.

Having now described the method of liquating copper with lead, and the products which result from the operation, I will endeavour to point out as briefly as possible the influence which this process has had on the purity of Japanese copper.

The aim of the process is the separation of silver from copper, and to the success with which this is accomplished by it, it chiefly owes its importance and value in Japanese metallurgy. But another and almost equally important result accompanies its use, *viz.*, that by it copper containing arsenic, antimony, and bismuth is either entirely freed from these metals or has the proportions in which they are present so reduced that they no longer exercise any injurious effects on its physical properties or unfit it for use as a constituent of brass or other alloys. The action of the process in removing these metals may be explained as follows:—

Under the conditions which prevail lead does not form a definite alloy with copper. When the two metals are melted together in the first stage A, only a mixture, and not an alloy, results.

During this melting, however, there would seem to be a transference of the arsenic, antimony, silver, and bismuth from the copper to the lead, so that the copper-lead mixture, after being rapidly cooled, may be regarded as a solidified lead solution of the silver and bismuth as metals, of the arsenic and antimony as an arseno-antimonide of copper and lead, and through which comparatively pure copper is disseminated in granular or crystalline particles.

When this mixture is heated in the second stage B, and it is important to remember that the temperature never reaches the fusing point of copper, the lead solution of the silver and bismuth trickles away from the spongy agglomeration of the particles of copper into the receiver prepared for it, but as its temperature is lowered as it leaves the copper at the upper end of the hearth below that required to retain the shiromé in solution, this substance is gradually deposited there.

The greater part of the arsenic and antimony separates out in the form of this pseudo speise. The whole of the bismuth, excepting mere traces, and nearly all the silver, passes into the liquated lead.

I am not acquainted with any other furnace process by which bismuth can be removed from the metal copper. The percentage when much is present may indeed be reduced by prolonging the ordinary process of refining, but more than traces are always retained by the copper.

It is important to note that when the lead is subjected to the subsequent cupellation process much of the bismuth passes into the silver, communicating to it the greatest brittleness. As, however, a simple furnace operation suffices for its removal it is no longer a source of trouble to the metallurgist.

Several kinds of Japanese copper which have, and deservedly so, a high reputation for purity, would, but for this process, be unfit for most industrial purposes, and in demonstration of this I will ask for your attention to the consideration of the following examples. The first, which is specially noteworthy, is the copper from the mine of Onodani (prov. Echizen), previously alluded to, which is obtained by smelting ores containing falherz and native bismuth. The falherz occurs in such quantities that the roasting heaps at the mine are incrustated with arsenious anhydride and realgar. Yet the Onodani copper is free from more than mere traces of arsenic and bismuth and entirely so from antimony, and has been long regarded as the best copper in

Japan for its malleability and ductility. In a recent report of the Director of Mines it is stated that it is the only copper now used in the Imperial arsenal for special copper work.

I have, unfortunately, no analyses of the metal before treatment by the liquation process, but from the composition of the *shiromé* obtained, given above, it must have contained about 0.20 per cent. arsenic and 0.08 per cent. antimony. The proportion of bismuth present would be variable, as the native bismuth is irregularly disseminated through the ore.

Its composition, after liquation and subsequent refining, is as follows:—

Antimony.....	Nil	Nil
Bismuth.....	Nil	Nil
Lead.....	0.119	0.252
	99.919	99.922

(In these analyses a ft. tr. of arsenic means that when 13 grms. of the copper were taken, no weighable precipitate of ammonium magnesium arsenate was obtained in the final solution (measuring 60 to 80 cc.) but merely streaks on the sides of the beaker indicating its presence).

Both analyses show a metal of great purity for copper which has not been electrolytically deposited.

The higher percentage of lead in the slab is intentional, as it is believed by the Japanese that the presence of lead in copper increases its malleability, and when it is not supposed to be present it is always added. The addition of lead to some kinds of copper have undoubtedly this effect, although the amounts sometimes added by the Japanese with excellent results so far as mere hand hammering is concerned, would be altogether detrimental to copper which had to be subjected to heavy forging.

The second example is a sample of copper which was sent to the Imperial Mint from one of the chief mines. I may say that before accepting any copper, or indeed, anything which could be chemically examined, I made an inflexible rule that it should be first analysed; a rule, the observance of which contributed largely to the success of many of the operations in the Mint.

This copper was partially analysed, and found to contain the following proportions of arsenic, antimony and bismuth:—

No. 7.

ASHIHO COPPER BEFORE LIQUATION.

	Per Cent.
Arsenic.....	0.26
Antimony.....	0.16
Bismuth.....	0.10

The injurious effects of bismuth, the *bite noir* of the copper refiner, on the ductibility and malleability of copper are well known. As small a quantity as 0.06 per cent. sometimes will cause commercial copper to be so red-short as to be quite unfit for any purpose where forging is necessary. The effects of arsenic and antimony on the physical properties of brass and some other alloys are not less familiar to metallurgists.

The above copper was hence promptly rejected as worthless for the manufacture of hammered or rolled articles on account of the bismuth present, and for the manufacture of brass on account of the arsenic and antimony. It was

then subjected to the liquation process at the works of the importer, after which it was again brought to the Mint, when on analysis it was found that these metals had been almost completely removed, the amounts present being as follows.

No. 8.

ASHIHO COPPER AFTER LIQUATION.

	Per Cent.
Arsenic.....	0.04
Antimony.....	Trace.
Bismuth.....	Trace.

These two examples, I think, sufficiently demonstrate the important influence which the liquation process has on the purity of copper.

Unfortunately it is not applicable in England owing to the high price of charcoal and labour, although several brands of copper in the London market which are contaminated with bismuth contain sufficient silver for their economic treatment in Japan.

The application of the by-product *shiromé* to practical uses exhibits well the ingenuity and skill of the Japanese as workers in metal. Alone it is worthless, but as early as the beginning of the last century they discovered that not only could it be used as a constituent of some alloys, but that by its addition certain valuable properties were conferred on them.

The first official record we have of its use is contained in an edict of the Japanese Government in 1761, prescribing its addition to the copper-lead bronze to be used in the Mint for casting "Do-sen," a small coin commonly known to Europeans as "copper cash."

In 1768 we have another edict directing the minting for the first time of brass coins called "shimon-sen" and the addition of *shiromé* to the alloy to be used. These two kinds of coins, as shown by the following analyses, hence contain considerable quantities of arsenic and antimony.

The analyses of another coin, "Bunkio-sen," which was chiefly a re-coinage of "Do-sen" in 1863, is also given.

No. 9.

The objects of its use in these cases were: to give additional hardness to the alloy without impairing its fusibility at moderate temperatures, and to obtain, when cast, a sharper impression of the mould than was possible with the copper-lead alloy alone. Additional hardness could also have been given by increasing the proportion of tin, but this would have had the disadvantageous effect of raising its melting point and of diminishing its fluidity when melted, both of which the Japanese desired to avoid, for two reasons—the first being that their crucibles, owing to the absence of a good refractory clay, were incapable of

sustaining long exposure to a high temperature, so that with metal of a high melting point they were soon worn out; and the second, that the coins were cast in very delicate moulds, made of a sand always more or less fusible, in which if metal with a high melting point was cast, the castings would be generally coated with a crust of semi-fused material not easily removable.

The specimens on the table demonstrate clearly the success with which the Japanese foundries contended with the difficulties inseparable from the want of a refractory clay and non-fusible sand by thus modifying the composition of their alloys to suit these unfavourable conditions. I do not think any other alloy would give equally good results so far as sharpness of impression, clean surface, and hardness are concerned.

During the latter half of the last century—probably from an earlier date—and up to the present time, shiromé has been largely used by the bronze founders of Osaka and Kyoto, the chief centres of the metal industries as a frequent addition to “Karakane,” a copper-lead bronze which is the principal alloy used in the manufacture of the numerous metal articles for ornamental and useful purposes in the production of which the Japanese are unrivalled. It is added to this bronze for the reasons given above for its addition to the old coinage alloys, but there is also another reason for its use, *i.e.*, it facilitates the production of the deep grey patina which is preferred for those vases or other objects which have to be decorated with inlaid line designs in silver (*zogan* work).

On the other hand, when a specially deep black patina was required in high-class bronzes, it was the practice of some of the best art founders to omit it from their mixtures for “Karakane.”

These last remarks apply solely to the older bronzes and not to the modern so-called “copies” of them.

In the old bronzes the colour and character of the patina is largely dependent on their composition.

On the other hand, in recent imitations—which however are not comparable with them in any way, excepting that they bear a slight but imperfect resemblance to them in superficial colouring—a false patina of almost any colour may be given to any copper alloy, irrespective of its composition, and even to unalloyed copper.

The following analysis of an old bronze (Karakane) incense burner (date 18th century) affords an example of the use of shiromé.

No. 10.

	<hr/> 99.66

From the proportion of arsenic present I should think that about 10 per cent. of shiromé had been used in making this alloy.

And here I wish to correct an error into which several writers have fallen who have accounted for the presence of arsenic and antimony in Japanese bronzes by assuming that it is due to the use of impure copper. Now no Japanese copper—and I have analysed some hundreds of specimens—ever contained, even when imperfectly refined, sufficient quantities of these metals to account for the percentages found in many bronzes.

The highest percentages I have ever found until the recent introduction of high blast-furnaces and modifications of European methods of smelting have been 0.085 per cent. arsenic and 0.090 per cent. antimony, and these amounts were quite exceptional. In fact, of all the samples received

at the Imperial Mint during 16 years 96 per cent. contained less than 0.015 per cent. arsenic, generally only a trace being present, and 97 per cent. had less than 0.02 per cent. antimony, this metal being usually absent altogether.

So that when arsenic and antimony are found in large proportions in the older bronzes their presence is due to their addition to the alloy in the form of shiromé, and not to the use of impure copper.

In some cases the arsenic has been added in the form of “Hakudo,” a Chinese alloy of copper and arsenic, but these are rare. An interesting example of this is afforded by a sword guard, the composition of which is taken from a valuable series of analyses\* of modern Japanese metal-work by my distinguished friend Prof. Roberts-Austen:—

SWORD-GUARD. COPPER ARSENIC ALLOY. (ROBERTS-AUSTEN AND WINGHAM).

Copper.....	98.060
Arsenic.....	1.066
Antimony.....	0.910
Lead.....	Nil
Bismuth.....	Nil
Iron.....	0.018
Nickel and cobalt.....	0.023
Zinc.....	Nil
Tin.....	Nil
	<hr/> 99.182

Another use for shiromé is as a cheap substitute for tin in the manufacture of metal mirrors, especially of the commoner kinds. This would seem to be a modern innovation, as in the older kinds I have not found arsenic and antimony in those proportions in which they would have been present had it been so used.

The following mixtures used in Tokyo are given in Ayrton and Perry's paper on “Japanese Magic Mirrors,” read before the Royal Society 2nd October 1878:—

Copper.....	81.3	71.5
Iyo shiromé (impure antimony) ..	2.4	..
Shiromé.....	16.3	28.5
	<hr/> 100.0	<hr/> 100.0

I have not, however, found such mixtures in use in the chief foundries of Osaka, tin always forming a constituent of their alloys, for the following reason: that when shiromé is used without any tin the mercury amalgam employed in silvering the face of such mirrors produces a surface which is deficient in brilliancy, is easily tarnished, and has but little endurance.

I have endeavoured this evening to describe a process developed by the old metallurgists of Japan, an interesting by-product obtained in it, and the uses to which this by-product has been put; and I am sure you will all agree with me that the skill and ingenuity the smelters and founders of Japan have shown in accomplishing the results I have somewhat imperfectly placed before you are worthy of our warmest admiration.

DISCUSSION.

Professor ROBERTS-AUSTEN said he had listened with the greatest possible interest to this account of the working of those consummate metallurgists, the Japanese. No one could possibly deal better with the subject than Mr. Gowland, who, he was sure, could give more than one paper on this subject if he would. No one knew better than metallurgists who had examined Japanese alloys how marvellous was the skill with which they added a minute quantity of what we should call an impurity for the sake of producing a definite result in the way of patina. The very smallest

\* Report on the analyses of various samples of Oriental metal work. Made under the direction of Prof. Roberts-Austen by Arthur Wingham, 1892.

quantity of gold would produce the most beautiful purple patina. He feared that in writing on this subject he might have said that the antimony and arsenic in Japanese alloys was not deliberately introduced, as they now knew to be the case, but found their way in from impurities in the copper. With regard to the process itself, Mr. Gowland said it was introduced into Japan in the middle of the 16th century, and the best account was that of George Agricola, who wrote in the middle of the 16th century, but that was not by any means the earliest period at which the process was known. There were earlier accounts of it, and quite recently, in some excavations made at Silchester, specimens of lead used by the Romans had been discovered, some of which were submitted to him and analysed by his assistant, and he thought there could be no doubt from their examination that in late Roman times this process of liquation was employed, and probably with success. There was one curious point about the bismuth, a very small quantity of which exercised a very deleterious effect on copper; some curious work which he did recently for the mechanical engineers showed that however small the proportion of bismuth in copper might be, it always remained free, it did not unite with the copper. It was possible by studying the cooling curves by means of an ordinary thermal couple to find veins of free bismuth, even although its amount did not exceed 0.1 per cent. or less. Mr. Gowland had thanked him for placing the laboratory of the School of Mines at his disposal, but seeing that Mr. Gowland had placed all the specimens there, the least one could do was to beg him to examine them *in situ*. He confessed he should have thought the introduction of the shiromé would have had a tendency to make the copper cash brittle, but that did not seem to be the case, and there was no doubt an extreme sharpness given by its addition. He should like to ask if the Chinese used similar alloys, and whether such Indian tribes as used coins of a similar appearance used the same kind of alloys.

Mr. CLAUDE VAUTIN said this very interesting paper had cleared away what was always a mystery to him, viz., the removal of the bismuth from copper, which, as was well known to everybody connected with copper, was a very serious impurity. If he understood the process aright, the explanation was something of this kind: in the melting furnace the copper and lead were both brought to a state of fusion, the mixture was then removed by plunging in a cold piece of iron on which a thin layer of the metal was, as it were, frozen; that was knocked off, the iron cooled, and again dipped into the mixture. In the melting furnace, while the two metals were in a fluid condition, no doubt there was a transference of the arsenic, bismuth, silver, and gold from the copper to the lead. The sudden cooling on the surface of the iron prevented the copper re-uniting with the bismuth and arsenic. Then in the liquation furnace the copper was never allowed to become in a fluid condition, and the operation of the workmen in front of the hearth consisted in pushing back, working up, or puddling the material. In so doing they gave the lead an opportunity of running away in exactly the same condition as it was in the melting furnace without the copper ever having been in a sufficiently fluid condition to re-absorb the bismuth, antimony, and silver. He should like to know if this was the correct rationale of the process; if so, it might have very important consequences. Personally, he was engaged a few years ago with a copper company in trying to remove bismuth from the copper, the presence of which reduced the value of that metal in the London market by 8*l.* a ton. On one occasion a remarkable result was obtained which unfortunately was never repeated, but of which he thought they had an explanation. They granulated some copper containing the bismuth and melted it with lead; he did not think it was quite fused, but the crucible was put on a slab and suddenly cooled, so that the copper set more rapidly than usual, and the lead when examined was found to contain most of the bismuth. They never got the same result when the copper was brought to a state of fusion. If this were the explanation it would be possible to introduce the operation at certain copper mines where there was difficulty in removing the bismuth, and in

this way produce good copper and make the mines pay. If this proved to be the case they would be very deeply indebted to Mr. Gowland for having placed these important facts before the Society. On looking over the analyses, he noticed that traces of gold were remarked in all the by-products, and in the first analysis one went as high as 26 oz. per ton. Would the gold follow the silver right through the whole operation?

The CHAIRMAN said that people in the West were rather apt to think that Easterns did not understand their own business, but this paper showed the importance of an observant eye, and proved that they did understand their business perhaps better than we did.

Mr. GOWLAND, in reply, said that in the sixth and seventh centuries the Chinese used a similar copper-lead alloy, and the first Chinese coins were made in imitation of that. The latter Chinese coins were nearly all of brass. He did not know that Professor Roberts Austen had stated that the arsenic in bronzes was due to impurities in the copper, and did not think he had—he was referring to some other writers. With regard to the reasons for the removal of the arsenic, bismuth, &c., he thought it was entirely due, as Professor Austen had pointed out, to the bismuth not alloying with the copper. It remained fused throughout the mass of copper, and then in this process of liquation the copper was never melted. It was just like a sponge, and the bismuth and arsenic were squeezed out along with the lead. With regard to the gold, he always put down gold as present in traces when on taking 20 grms. there was no weighable quantity although its presence was indicated. With regard to copper containing 40 oz. to the ton, that was peculiar to one of the mines in Japan. They produced it in large quantities from 10 to 20 tons or more per annum. This copper containing 40 oz. per ton was brought to the mint as common copper, they being quite unaware that it contained gold until he sent the assay report; in fact, however, the gold was much more valuable than the copper. In treating copper containing gold by the liquation process, only a part of the gold was removed; it did not all go with the silver; a portion went, but a variable quantity remained behind in the copper.

MR. LUSACE CAREY IN THE CHAIR.

# TREATMENT OF CUPREOUS IRON PYRITES AS CARRIED ON AT THE PORTUGUESE MINES.

BY J. HENRY BROWN.

THE most important of the Portuguese mines is that of San Domingo, worked by Messrs. Mason and Barry. The next in point of importance are, in the south, the Aljustrel, Grandola, and Brancannes mines, and in the north those of Palla and Telhada. More recently the mines actually engaged in work are the San Domingos, Brancannes, Palla, and Tinoca mines.

The first named is the most important mine, and has for a number of years supplied by far the greatest amount of sulphur ore put into the market.

Since the year 1884 the export of crude ore has ceased, the whole production being treated locally.

There is and always has been a notable difference in the preliminary processes carried on at the Spanish and Portuguese mines. This of itself is a very noteworthy feature.

In Portugal, unlike the neighbouring country, there are certain restrictions in the way of dealing with the mineral, and stringent regulations relating to the disposal of the waste product in the way of liquors.

Owing to the importance of the sea and river fisheries, it is not allowable to send waste iron (from copper precipitation) liquors into the streams at will. Wherever the configuration of the country allows, liquors have to be held back in enormous reservoirs until such time as the river shall be in heavy flood, which is generally in winter or early spring.

The burning of the mineral has been out of the question owing to local opposition and the impossibility of getting over the compensation question. Even where such difficulties might have been overcome, the question of disposal of waste liquors has been a difficulty. In some places the natural surface of the country does not allow of the formation of "holding-back" reservoirs, and for this reason the treatment of cupreous iron pyrites by the humid process has not been possible.

There are two distinct methods of treatment in use at the various mines:—

(1.) "*Burning the Mineral in the open.*"—This method has been practised to some extent at the mines of Aljustrel, but has only been tried on an experimental scale at those of San Domingo.

The process is rapid and has the advantage of yielding liquors on lixiviation containing comparatively a small amount of arsenic. The disadvantages of the process are that it is wasteful and involves a considerable loss of sulphur; it also leaves on lixiviation a residue of no commercial value, thus causing the accumulation of vast deposits of spent material. The spread of this process has been prevented in many instances by the opposition of the agricultural interest in the surrounding country.

(2.) "*The Weathering Process.*"—This process was first initiated at the San Domingo works of Messrs. Mason and Barry, and in spite of the fact that the process is slow and the liquors on lixiviation are rich in arsenic, which is thrown down with copper on treatment with metallic iron, it is still largely and successfully employed.

It is carried out somewhat as follows:—The ore from the mine undergoes a careful scrutiny for the purpose of selecting the most suitable for "weathering." That of a hard nature and a close texture is rejected; it generally has a low assay, and is further unsuitable for process because of not being able to absorb water.

Again, mineral containing copper pyrites is likewise rejected, although the assay is probably very high. The reason for this is that this class of mineral is also very hard and impenetrable to the action of water, and would yield no result at process, *i.e.*, not give up its copper.

Having selected the best ore for treatment, it is loaded into waggons and trammed away to the sites where the heaps of ore may undergo the "weathering" process.

The heaps are formed of from 100 to 250,000 tons of mineral, varying in assay from  $1\frac{1}{2}$  to 2 per cent. copper. These figures on the larger quantity named would give 3,750 tons, and 5,000 tons total fine copper. As a matter of fact about 88 per cent. of the total copper present is exhausted in the course of six years, therefore 3,300 and 4,400 tons is the yield; the balance is not recoverable except by long and unprofitable continuance of the treatment.

This seems a long time to bring about this result, but it must be remembered that enormous quantities of ore are at some places under treatment. At San Domingos this amounts to 3,000,000 tons, and if only  $\frac{1}{100}$  of a per cent. be extracted per annum, there would result an annual production of 3,000 tons fine copper; a more likely figure would be  $\frac{1}{2}$  per cent., corresponding to a produce of 6,000 tons per annum.

Plenty of stone flues are distributed on the surface of the natural ground, and the mineral is tipped on the top. These flues are connected one with another longitudinally and transversely, and at certain intervals with the outer air by vertical pipes or stone shafts. The object of all this is to provide a plentiful supply of air for the promotion of oxidation. This action goes on with wonderful rapidity and at times with such violence that water must be applied to prevent the heaps taking fire.

Such a state of things is very detrimental, as the ultimate denudation of the copper contents is prevented by reason of the formation of masses of agglomerated mineral.

For lixiviation of smalls it is best to use water by a sort of irrigation scheme, *viz.*, condensing it about in channels into small receptacles or shallow tanks, from which the water gradually drains away through the mineral.

Under these circumstances it is clear that great altitude of the heaps is desirable; the same volume of water serves for washing a 10-metre-high heap as a four-metre one. The use of water only becomes very much increased when the area covered is very great in proportion to the altitude attained. Thus it is economical to have deep heaps, for there is less water used, better liquors produced, and less space to be sought for the construction of these heaps.

By judicious treatment the already-mentioned untoward symptoms may be avoided, and by a careful alternation of application of water and competent rest for the re-establishment of the lost heat of the heap, 88 per cent. of the total copper may be extracted in the reasonable time of six years.

There is a further source of copper manufacture, that of pumping the natural drainage, rich in soluble copper, from the mine. These liquors being very free from ferric salt make remarkably good precipitate. At the mines of Messrs. Mason and Barry this feature has been very much developed by systematic flooding of the opencast as the workings have progressed. This has resulted in an enormous yield of cheaply-made copper.

For the treatment of a few million tons of process ore in a large metallurgical establishment, there must of a necessity be large supplies of fresh water stored in dams. These are filled by draining the adjoining country. By preference it is better to have the heaps of mineral under treatment at lower levels than the water supply, which can then be run to them by gravitation.

After undergoing the above-described process for a space of time, the copper contents are reduced to so low a figure that any further continuation of the treatment would be unproductive. The ore by this time has become very much disintegrated, and at such mines as are favourably situated for economical carriage and facilities for shipment, the residual small ore is exported in large quantities, being used extensively in the production of vitriol. The percentage of sulphur in the remaining smalls is but little inferior to that in the crude or untreated ore.

Previous to precipitation, or cementation, as it is called, of the copper on to pig iron, it is necessary that the liquors should be purified. There are three constituents which consume iron, *viz.*, the copper, free acid, and ferric salts; the two latter, especially the last, if present in excess, lead to

an immense consumption of iron, because of its subsequent reduction to ferrous salt by the agency of free acid and iron.

It is requisite for economical work that before precipitating the copper, the ferric salt should be as completely reduced as possible. This has in time past given much trouble.

It is now very effectually removed by filtering liquors through rich assaying cupreous sulphur smalls; the ferric salt is thereby completely reduced to the ferrous state. The operation is carried on in large dams, where the liquor may be kept some time in contact with the smalls. The following equation represents the reduction effected:—

The liquors to be treated are run through a series of settlers for the purpose of retaining any fine suspended matter, and are then brought into the precipitating plant.

This, in modern establishments, consists of a series of wide but shallow canals, constructed of either timber or brickwork, and of great length, being arranged that the liquors run through at great speed.

A fall of 1/100 amply suffices for this, but in some places they give the liquors when well stripped of copper, a fall of 1/50.

The canals may conveniently be 4 ft. wide and 8 to 10 ins. deep; pig iron is then placed in them in a methodically stacked manner, leaving plenty of interstices for the passage of liquor.

Probably most of the copper precipitate produced in Portugal is after proper preparation exported to England. There are in the former country no extensive smelting works for the treatment of precipitates or ores of copper; the high price of fuel evidently precludes any operations of this kind.

At the present time, unremunerative prices of copper have brought about a stagnation in the production of cupreous iron pyrites in Portugal.

## METHODS FOR THE RECTIFICATION OF VITRIOL. A NOTE.

BY FRANK TATE.

SINCE the publication of my paper on "Methods for the Rectification of Vitriol" (this Journal, 1894, pages 206—211), Mr. William Garroway, of Glasgow, has called my attention to a patent taken out by him for "Apparatus for the Manufacture and Concentration of Sulphuric Acid," Specification No. 1673, 1883. The specification states that the improved apparatus comprises a series of open beakers, basins, or tubes of hard Bohemian glass or glazed ware of cylindrical form, which are fitted into a flue or flues and so connected together that acid or liquor may be caused to flow continuously through the series. The beakers may be placed in an inclined flue or in a long compartment, and may be connected together by glass siphon tubes; or, in a modified arrangement, the beakers may be formed with a projecting lip or spout on one or both sides and arranged on steps or on a slope in the flue so that the liquid entering the highest beaker of the series overflows into the second, and each in turn flows over into the next in order continuously.

Mr. Garroway says "this system of concentrating sulphuric acid has been working here (*i.e.* Netherfield Works, Glasgow) for years. The wear and tear is very slight, with hardly any breakages of the beakers."

## INDIA RUBBER (A CRITICISM).

BY WILLIAM THOMSON.

ON the 5th of January a paper was read before this Section by Mr. C. O. Weber on india-rubber, but with special reference to its vulcanisation, in which he brought a considerable amount of criticism against work which I had done and which I think requires a reply. I desire therefore to lay before you to-night a paper giving my criticism of his paper.

He confirms the observation of Tilden that isoprene polymerises into india-rubber. Tilden says: "Isoprene is a very volatile liquid boiling about 35°. Its molecular formula is  $\text{C}_5\text{H}_8$ , and it forms a tetrabromide  $\text{C}_4\text{H}_6\text{Br}_4$ ." Weber says he had some isoprene which he kept for nine months, it had polymerised into india rubber; which he precipitated by methyl alcohol. The alcohol kept in solution "a thick oil boiling at 245° C., and combining with bromine with formation of a tetrabromide."

Weber does not state of what it is a tetrabromide.

He goes on to say that this thick oil is composed of a mixture of substances, 20 per cent. of dipentene (which he has previously informed us boils between 168° and 176° C.)—a large range of difference for a pure substance. The rest, he says, is a mixture of two substances, which, so far, he has failed to separate, because fractional distillation did not avail; and yet the mixture of these three substances, 20 per cent. of which boiled at 170° or thereabouts, had a boiling point, he informs us, of 245° C.

He presumably separated the dipentene from this mixture of three bodies and left two bodies. (I should like to know how he ascertained there were only two bodies present), but for the sake of argument I will assume there were only two; he states that he determined the molecular weights of the mixture of these two substances by Beckmann's freezing-point apparatus, and he remarks that the results he obtained "strongly indicate this mixture to consist of condensation products of the formula  $\text{C}_{25}\text{H}_{36}$  and  $\text{C}_{40}\text{H}_{64}$ ."

I have understood that in using Beckmann's apparatus an important condition was that the substance under test should be pure. It would be interesting to know how Weber obtained any formula at all from such an experiment, and still more interesting to know how he succeeded in finding any indication of the formulae for both.

Tilden, in his paper (Chem. News, Vol. 65, p. 265), says, the constitutional formula of isoprene is not known with certainty, but it must be selected from the five following formulae, three of which he classes as "derivatives" of

allene, " $\text{CH}_2 = \text{C} = \text{CH}_2$ ," and two as derived from crotonylene,  $\text{CH}_2 = \text{CH} - \text{CH} = \text{CH}_2$ ." I should like you to contrast Weber's statement with this. He says:—

"At the present time the constitution of isoprene itself is very doubtful. We only know that it contains two ethylene bonds, and for that reason must be a derivative either of allene,  $\text{CH}_2 = \text{C} = \text{CH}_2$ , or of vinyl ethylene,  $\text{CH}_2 = \text{CH} - \text{CH} = \text{CH}_2$ ."

Whilst pointing out the fact that india-rubber is in some way connected with isoprene ( $\text{C}_5\text{H}_8$ ), he admits that we do not understand the constitution of that body and therefore, as he says, that does not help us in arriving at any idea as to the molecular constitution of india-rubber; but after pointing out that isoprene and also di-pentene contain two ethylene bonds, he concludes that india-rubber differs very essentially from the terpenes and polyterpenes as at present understood.

I have always been under the impression that there was a great difference between the "absorption" of sulphur by india-rubber, and the chemical combination of that body with it, but Weber puts it that various writers describe vulcanisation as an "absorption" of sulphur. India-rubber is capable of absorbing sulphur without becoming vulcanised. Bolas says it will absorb 50 per cent. by putting it in a bath of melted sulphur without becoming vulcanised in the slightest degree.

After discussing the question as to whether sulphur produces an "addition" or a "substitution" product, and then—speaking of the action of chloride of sulphur on india-rubber, for which he says Burghardt gives a rational explanation by saying that the displaced hydrogen combines with the chlorine of the chloride of sulphur, forming hydrochloric acid, which Weber afterwards says really does not happen—he goes on to say "diametrically opposed to these statements is Thomson, who gives it as his opinion that the vulcanising action of chloride of sulphur is due to the chlorine, and not to the sulphur of the compound. He asserts that india-rubber vulcanised with chloride of sulphur contains only *minute traces of sulphur* as an impurity, but large quantities of combined chlorine, and that the same is the case with the oils converted into india-rubber substitute by means of chloride of sulphur."

In answer to this, I give, as follows, an extract from my paper to which he refers. "Recently I analysed three samples of rubber substitute . . . the first contained of sulphur 3.4, and of chlorine 7.6 per cent. The second contained of sulphur 4.56, and of chlorine 8.22 per cent., and the third 2.67 of sulphur, and 7.90 of chlorine." Weber does not seem to recognise that there are two chlorides of sulphur in commerce, the "yellow" and the "dark," and that the yellow chloride often contains a considerable quantity of the dark sulphur di-chloride. According to Fawcitt's figures, the dark chloride contains about 52 per cent. of the di-chloride, which would give a product containing a much larger quantity of chlorine than the mono chloride, and this body might have been used in producing the vulcanised oil which I analysed.

I think I was the first to point out that, after vulcanising with chloride of sulphur, both sulphur, and chlorine were afterwards found in chemical combination in the rubber and in the substitute, and I simply accentuated the fact that in the analyses I made I found more chlorine than sulphur.

The presence of these two bodies in chemical combination was not previously recognised, and Weber, whilst acknowledging afterwards that both bodies enter into combination with the rubber, goes on to say: "Thomson's results were considered rather startling when first published, but I think his analytical method by which he obtained them is more startling still, and I consider it a matter of great surprise that it never has been challenged. This method consists in fusing the vulcanised rubber or rubber substitute with caustic potash, dissolving the melt in water, &c." . . . "It is a matter of surprise that Thomson should have found any sulphur at all in those compounds."

I might refer him to various works on organic chemistry which actually give the process which he condemns in such unmeasured terms. I would refer him, for instance, to Berntsen's *Organische Chemie*, page 6. There it suggests

fusion of organic substances containing sulphur with caustic soda and of a small quantity of an oxidising agent, which is of course necessary when no further precautions are taken, such as by the use of hydrogen peroxide, which I adopted for conversion of the whole of the sulphur compounds contained in the soda mixture into sulphates.

He proceeds, however, to say: "at any rate before applying" that process "to the analyses of these unknown compounds, its suitability for the purpose ought to have been tested. After this, neither the method nor the startling results it furnished would ever have got into print." In reply to this criticism I may say that I tested the process against the one which I had previously employed, viz., by decomposing the organic compounds by means of fuming nitric acid in hermetically sealed tubes heated under pressure, and finding the results agreed well, I adopted the soda process as the much simpler one of the two.

I asked Dr. G. R. Winder if he would kindly repeat the process described by Weber as absurd, in comparison with the nitric acid process, and give me the results, without giving him any reasons for it. He reported as follows:—

At your request I have made determinations of the sulphur contained in the two samples of india-rubber substitute which you gave to me: (a) by the nitric acid method, and (b) by fusion with caustic soda and subsequent oxidation of the solution obtained from the melt.

(a.) The nitric acid method was carried out by heating 7 grains of the substance with 240 grains of fuming nitric acid in a hermetically sealed glass tube which was heated to 265° F. during the first day. The tube was opened at the capillary end after allowing it to cool, and the  $\text{CO}_2$  allowed to escape; it was resealed and further heated to 345° F. during the second day, again opened and resealed as above described, and again heated during the third day to 385° Fahr. On opening on the last occasion practically no pressure was found, although I had a large excess of nitric acid left. The contents of the tube were then washed out, diluted with water, and the sulphuric acid estimated by means of barium chloride in the usual manner.

(b.) The caustic soda method was carried out by mixing about 10 grains of the india-rubber substitute with finely powdered caustic soda, and fusing in a silver capsule, dissolving the melt in water, oxidising with a few drops of bromine, slightly acidifying with nitric acid, and precipitating with barium chloride. Peroxide of hydrogen would of course answer the same purpose, but I had none at hand which was quite pure. The following results were obtained:—

	Per Cent. of Sulphur India-rubber Substitute.
By nitric acid process . . . . .	7.87
By caustic soda process . . . . .	7.91

The second sample tested in the same way gave in duplicate:—

	Nitric Acid Method.	Caustic Soda Method.
	Per Cent.	Per Cent.
Sulphur, first determination . . . . .	8.29	8.66
" second " . . . . .	8.33	8.72

You will observe that the sulphur given by the caustic soda method is rather higher than that obtained by the nitric acid process; that I account for by the fact that Dr. Winder precipitated his barium sulphate from a dilute nitric acid solution, the presence of free nitric acid preventing the complete precipitation of the barium sulphate.

All I was told about the samples of rubber substitute which I analysed was that chloride of sulphur had been used in their manufacture. What kind of chloride of sulphur or what kind of oil was employed, or whether that oil was first oxidised, I had no idea. The point I wished specially to make was that, contrary to the generally accepted ideas, chlorine as well as sulphur entered into

combination with the organic compounds, producing vulcanised rubber or vulcanised oil, and this my critic entirely overlooks.

Weber, having summarised what others had done, proceeds to give his own work, as he puts it, "with a view to arrive at a definite settlement of these points, and at the same time to clear up the chemical mechanism of the vulcanisation process in general."

After considering the work of Guthrie, who showed two ethylene and two amylene molecules, after being acted upon by chloride of sulphur, as being joined together by the two atoms of the diad element sulphur, with the two atoms of the monatomic element chlorine, attached each to one carbon atom of each of the molecules, ready to go off on the slightest provocation, he goes on to say that "quite recently Ulzer and Horn, and especially Henriques, proved conclusively that these india-rubber substitutes contain sulphur and chlorine in the same proportions in which they form chloride of sulphur." He goes on to say, "These results are of course directly opposed to Thomson's figures, which, however, have been obtained by such a questionable method that they cannot be taken seriously."

Now, I wish to call your attention to Henriques' results, and as they have been translated by Weber himself he ought to be thoroughly acquainted with them. They do not show that sulphur and chlorine exist in the proportions in which they exist in chloride of sulphur. The first line of the following table gives the percentage of sulphur and chlorine respectively in chloride of sulphur ( $S_2Cl_2$ ), which Weber assumes Henriques employed. The figures underneath show the relative quantities of chlorine to sulphur found in five different samples of substitute examined by Henriques, and the third column of figures shows the difference between what was found and what ought to have been found if the assertion, which Weber says has been "conclusively proved," were correct.

HENRIQUES' ANALYSIS OF INDIA-RUBBER SUBSTITUTE.

	Quantities of Sulphur and Chlorine present.		Percentage of Differences from the Theoretical Quantities.
	Sulphur.	Chlorine.	
In chloride of sulphur ( $S_2Cl_2$ )	47.41	52.59	0
White Substitutes:—			
A .....	56.14	43.86	+ 8.73
B .....	51.28	48.72	+ 3.87
C .....	48.16	51.84	+ 0.75
Castor-oil Substitutes:—			
With minimum of $S_2Cl_2$ .	41.84	58.16	- 5.57
With maximum of $S_2Cl_2$ .	54.22	45.78	+ 6.80

These figures show from 5½ per cent. of sulphur to chlorine below the theoretical proportion to 8½ per cent. above it, and whilst Weber says that Henriques has proved conclusively that these india-rubber substitutes contain sulphur and chlorine in the same proportions in which they form chloride of sulphur, Henriques himself says: "On the action of chloride of sulphur on oils very little is known," and asserts that "part of the fatty acid of the substitute must therefore be contained in it in the form of a sulphonic acid produced by some oxidising influence upon the chloride of sulphur"; and further he says, when chloride of sulphur acts upon oils part of it is converted into sulphurous and hydrochloric acids."

Weber then goes on to explain how he made an experiment to determine whether hydrogen was liberated on treating a solution of india-rubber in benzene with chloride of sulphur, and finding that no hydrogen was liberated he remarks:—

"Already now it can no longer be doubted that Fawsitt's observations of an evolution of hydrogen in this reaction

must be erroneous as well as the statements of Burghardt, Terry, and Thomson, respecting evolution of hydrochloric acid." By this he assumes that I have said that hydrochloric acid is liberated when chloride of sulphur acts on india-rubber. I state precisely the opposite. I say in my paper "In the cold vulcanisation process it is generally supposed that the chloride of sulphur breaks up, the chlorine combining with the hydrogen producing hydrochloric acid which is liberated. This reaction is clearly not the correct one."

With a view of elucidating this subject further, Weber makes two experiments, both of the same character, in which he treats rubber dissolved in benzene in the proportion of one gram of rubber to one gram of chloride of sulphur, and he obtains a compound which on analysis he finds to be a body of very definite composition, viz.,  $C_{10}H_{16}S_2Cl_2$ . Now india-rubber consists of two distinct bodies, the one more soluble in benzene or in carbon bisulphide than the other, yet he finds these two bodies (according to his analysis) to be one having the composition above mentioned. He admits that india-rubber does not act like a definite chemical substance, because a small quantity of chloride of sulphur equal to say 5 per cent. of sulphur on the rubber employed, converts the whole into a homogeneous body insoluble in the usual solvents, whilst you can go on adding chloride of sulphur as it were drop by drop, each drop acting upon the whole rubber present producing always a homogeneous compound till you have ultimately converted the whole into a hard substance or vulcanite. He does not try the effect of two grms. of chloride of sulphur, for instance, to one gram of rubber; had he done this it is probable that he would have obtained a compound which would not have given on analysis results so wonderfully in accordance with any formula.

He then goes on to state that when pinene-nitroschloride is boiled with alcoholic potash the chlorine is eliminated and the appearance of the product is not altered, and from this he argues that when india-rubber is similarly treated the result must be the same. Fawsitt says (this Journal Vol. V. p. 640) "These samples show on examination that the yellow chloride of sulphur acts quite differently from the dark; there is no tendency with the former to harden the rubber even although used as strong as 1 to 15 (of carbon bisulphide) whilst with the latter 1 to 60 has such a tendency and renders the rubber inelastic."

This hardening of the rubber being due to the presence of chlorine in the molecule, I presume, according to Weber, that the hardness should be removed by boiling in alcoholic potash. This suggests two points: first, he might have tried the experiment before making such very definite statements; and second, what formula would he assign to this rubber which has been so hardened by excess of chlorine?

He states that chlorine does not vulcanise rubber, because, although halogen derivatives of india-rubber resemble the vulcanised material, they are clearly distinguished from it by their great and complete solubility in benzene and chloroform. From this it appears that according to Weber the object of vulcanisation is to render the rubber insoluble in benzene, &c. I have always understood that the object of vulcanisation was to keep rubber soft at low temperatures and to prevent it from becoming plastic at the higher temperatures. If the halogens effect this I should say they vulcanised the rubber, and if the rubber so vulcanised were soluble in benzene that would be a great advantage in enabling old vulcanised rubber to be remanufactured. I have, however, in this bottle of benzene some of Fawsitt's rubber vulcanised by the iodide of antimony, and you will see that it is quite insoluble. Further, I dissolved india-rubber in carbon tetrachloride and then passed chlorine through the solution which became warm and at the same time gradually precipitated the chlorinated compound as an insoluble jelly. The excess of chlorine passed through the tetrachloride solution was then conducted through a small quantity of water in a test tube to find whether any hydrochloric acid was produced. This would have been indicated by a rise of temperature in the water, but the water remained quite cold during the experiment, and when the carbon tetrachloride was examined no indication of the production of hydrochloric

acid was noticed either by the fuming produced when hydrochloric acid is present or by the smell. These results show, I think, that Weber was mistaken in his observations on the action of solvents on the halogen compounds of india-rubber.

Having proved to his own satisfaction that india-rubber combines with a maximum amount of 23.8 per cent. of sulphur and 26.1 per cent. of chlorine, Weber finds that 4.26 per cent. of sulphur and 4.71 per cent. of chlorine completely vulcanises the whole mass. This he arrives at by taking the experiments of Henriques, who showed that rubber vulcanised with chloride of sulphur so as to leave in it 5 per cent. of sulphur was rather over-vulcanised, whilst rubber containing a tenth of that quantity was under-vulcanised. On such data does he venture to predict the molecular constitution of rubber. He assumes a rubber containing 4.26 per cent. of sulphur to be properly vulcanised, and he calculates if 23.8 per cent. represents the molecule as  $C_{10}H_{16}$ , then 4.26 per cent. of sulphur would represent a total molecular weight of 1,300, and this almost exactly corresponds to  $C_{10}H_{16}S_2Cl_2$ . It might, however, with equally good reason be taken as Fawcitt gives it, that rubber vulcanised by chloride of sulphur so as to contain 0.791 per cent. of sulphur is well and properly vulcanised and this on the basis in question would bring the molecular weight up to over 8,000, thus making the molecule about  $C_{10}H_{16}S_2Cl_2$ . I am quite sure, as Weber puts it, that the molecular weight for india-rubber which he has deduced will not be accepted without comment, or even with it. In short, I think his ideas of india-rubber are altogether at variance with the character of the material whose molecular weight he has been trying to determine.

#### DISCUSSION.

DR. CARL OTTO WEBER said in reply: this paper of Mr. Thomson resolves itself into a criticism *a tout prix* of my paper, and some of his arguments appear to be based upon an utter misconception or disregard of my words. His remarks about isoprene ascribe to me claims I never raised. Why Mr. Thomson should wonder, in the face of Gladstone and Hiltbert's paper, that I express myself with some reserve with regard to the constitution of india-rubber as a polyterpene, I am at a loss to understand. After taking my remarks on Burghard's view of the vulcanising action of chloride of sulphur to be an acceptance of them, he proceeds to furnish proof of the correctness of his analytical method by quoting the results obtained by Winder in testing it against Carus' nitric acid method. That results so satisfactory as those can be obtained I do not doubt; but I maintain that in working Thomson's method without such a check, the results must always contain an element of considerable uncertainty, as they are apt to show most unaccountable variations. This is not my experience alone, for if anyone has proved it, Thomson has done so himself by his own analyses, in which he finds only from one-half to one-third the amount of sulphur observed by Dr. Winder. That commercial chloride of sulphur sometimes contains small quantities (never exceeding 6 per cent.) of  $S_2Cl_2$  is no explanation of the exceedingly low percentages of sulphur he observed, as, even by preparing india-rubber substitutes with pure  $S_2Cl_2$ , his figures could not be correct. Altogether, I insist that, in whatever manner prepared, there is not, nor ever was there, an india-rubber substitute in existence containing such small amounts of sulphur as observed by Thomson. In india-rubber vulcanised by  $S_2Cl_2$ , Thomson finds 2.6 per cent. S and 6.31 per cent. Cl, and I maintain that these figures are also absolutely impossible as far as the percentage of sulphur is concerned. In vulcanising with chloride of sulphur a loss of chlorine might under certain circumstances occur, but no sulphur can escape. The loss or deficiency of sulphur shown in Thomson's analyses is simply due to his method of estimating it. For this reason all the conclusions Thomson derived from his figures are necessarily erroneous. The severe manner in which Thomson criticised the formula  $C_{10}H_{16}S_2Cl_2$ , which I calculated for the compound obtained on the interaction of 50 grms. of india-rubber and 50 grms. of chloride of sulphur, would have been justified if he had

proved that by using 60 grms. of chloride of sulphur or more, compounds of an altogether different composition are obtained. This, however, is not the case, provided the concentrations given by me are adhered to. Nevertheless, I have reasons to believe that even compounds  $C_{10}H_{16}(S_2Cl_2)_2$  and  $C_{10}H_{16}(S_2Cl_2)_3$ , corresponding to  $C_{10}H_{16}Br_4$  and  $C_{10}H_{16}Cl_6$ , can and do exist, but this forming partly the subject of my next paper, I will not discuss this point any further to-night. Thomson missed the only undoubted chance my paper affords him for correcting me, and this is with regard to the statement I made that the whole of the chlorine can be eliminated from the compound  $C_{10}H_{16}S_2Cl_2$ , by boiling it with alcoholic potash, which should read potassium ethylate, *i.e.*, a solution of metallic potassium, not potash, in alcohol. Thomson next goes on to criticise the manner in which I arrived at the formula  $C_{10}H_{16}$  for india-rubber, taking, however, not the slightest notice of the important experiment with mixtures of  $C_{10}H_{16}S_2Cl_2$  and unvulcanised india-rubber. He also overlooks that I distinctly stated the probability of even that formula still requiring to be doubled in order to express the true molecular weight of india-rubber. By passing a current of chlorine through a solution of india-rubber, Thomson obtained a compound which he found to be insoluble in benzene, and he concludes from this that my statement as to the solubility of india-rubber chloride in benzene is incorrect. His compound, however, can no more be described as india-rubber (hexa-) chloride, than a chloride of cymene could be called a terpene chloride. Gladstone and Hiltbert already showed that by passing a current of chlorine through a solution of india-rubber, substitution products of the latter are obtained, which indeed are insoluble in benzene. Thomson's suggestion that, according to my statements, india-rubber over-chlorinated in the vulcanisation process ought to be rendered soft and pliable again by abstracting the excess of chlorine, is due to a similar misunderstanding. In abstracting chlorine from an addition product of chlorine and india-rubber, we invariably deprive the molecule of an equivalent amount of hydrogen, so that the eventual result is again a compound as different from india-rubber as cymene is from terpene. I certainly did not say that the object of vulcanisation was to render the india-rubber insoluble in benzene, but pointed out that the solubility of the halogen addition products of india-rubber, coupled with their general chemical instability and their sensitiveness against changes of temperature, sharply distinguished them from vulcanised india-rubber. Even Fawcitt's vulcanisation with iodide of antimony proves nothing to the contrary, and, from Thompson thinking that it does, I must infer that he has not studied the vulcanising action of this compound, which is most interesting, and which I will explain in my next paper on the subject. The chemistry of india-rubber offers a vast field of work to chemical investigators, whether from a purely scientific, technological, or analytical point of view.

Meeting held Friday, 4th May 1894.

MR. IVAN LEVINESTEIN IN THE CHAIR.

#### ON THE ANALYSIS OF INDIA-RUBBER ARTICLES.

BY CARL OTTO WEBER, PH.D., F.C.S.

WITHIN the last two years considerable progress has been in the analysis of india-rubber articles, chiefly owing to the successful exertions of R. Henriques (this Journal, 1893, 467) in this direction. There are, however, still a great number of moot points to be settled by further investigation before we shall have arrived at a thoroughly reliable and satisfactorily workable method of analysis of these very complex compounds and mixtures. Terry, in a paper read before this Society (this Journal, 1892, 970),

expresses an opinion that from the fact of no analytical methods for the analysis of india-rubber articles being known, it should not be inferred that they do not exist. But he does not tell us what these methods consist in, and I must confess to a deep-rooted suspicion against secret analytical methods. However, I believe that I possess a knowledge of the method Terry was hinting at, and I shall show later on that it was all the better for being kept secret, its secrecy being indeed its strongest point.

Before Henriques published his investigations on this subject, the analysis of india-rubber articles essentially consisted in the estimation of the ignition residue of the samples, the nature of the organic matter either not being considered at all, or vaguely supposed to represent india-rubber of some kind. The determination of the residue on ignition of a sample of an india-rubber article does hardly deserve the name of an analytical method; it is at best a rough-and-ready test. With regard to the estimation and separation of the organic constituents of manufactured india-rubber, it appears that no serious attempts have ever been made to overcome the numerous difficulties and solve the many vexed questions involved in this task.

It is well known that the majority of india-rubber goods are not manufactured from pure india-rubber only, but contain, besides mineral matters, more or less considerable quantities of india-rubber substitutes (oil substitutes), recovered rubber, various bituminous substances, resins, paraffin wax, resin oil, mineral oil, and sometimes even fatty oils. Almost completely overlooked was the fact that the various brands of india-rubber are by no means homogeneous compounds, but represent mixtures of hydrocarbons of the nature of india-rubber proper with variable quantities of resinous substances, which are of course also to be found in the manufactured articles. The proportions of hydrocarbon and resin vary greatly in different brands of india-rubber, but seem to be fairly constant for the same brand. The most noteworthy property of these india-rubber resins, which very likely are products of the oxidation of the india-rubber hydrocarbon, is the readiness with which they combine with large quantities of sulphur. Indeed, several of the inferior brands of india-rubber are said to be vulcanisable. This is, however, not intrinsically true, for although it may be found that they cannot be vulcanised with such quantities of sulphur as are supposed to be admissible for practical purposes, this is only on account of the resin taking hold of the sulphur before the india-rubber has time to combine with it. If we free such brands of india-rubber of their resin, vulcanisation of the rubber will no longer be found impossible.

On the resinous constituents of india-rubber, Terry (this Journal, 1889, 218) read some time ago a very interesting paper giving the percentage of resinous matter contained in various brands of india-rubber. His results were obtained by extracting the finely-cut india-rubber in a Soxhlet tube with alcohol. Having observed that this method is rather tedious, an excessively long time being required for the complete extraction of the resinous matters, I dissolved the dry samples of india-rubber (50 grms.) in 1,000 cc. of benzene, filtered through silk gauze, and added 100 cc. of the filtrate very slowly to 200 cc. of alcohol. The whole of the india-rubber was precipitated while the resin remained in solution. The latter was then filtered, the india-rubber remaining on the filter, washed with some hot alcohol, and subsequently the whole of the filtrate evaporated in a weighed flask.

As will be seen from the table in next column, some of my figures, especially those referring to the better qualities of india-rubber, agree very well with Terry's results. Most of my figures are, however, rather higher than that author's, but this may perhaps be due to variations existing between different samples of the same brand of india-rubber.

The melting points Terry observed for these resins are, as he suspects himself, of very little value; as a matter of fact in many cases the melting point can scarcely be determined with accuracy, owing to these resins without exception being mixtures of saponifiable resin acids and indifferent resins. A thorough investigation of these resins and their constituents, as well as of the resin-free india-rubbers would be most valuable, and, no doubt, also be

productive of important technical results, although I admit that from the point of view of chemical manipulation the subject is certainly not very attractive.

All these resins being readily soluble in alcohol and alcoholic posash, it is evident that some attention will have to be paid to them in the analysis of india-rubber articles. All the more so as in certain cases it may be possible to infer the quality or average quality of the india-rubber contained in an article, from the percentage of resin present. It must, however, not be forgotten that resinous matters may be formed in manufactured india-rubber by oxidation, as shown by Burchardt and Thomson, and it is doubtful whether these resins are any different from those occurring in the crude india-rubber. For this reason I content that Burchardt's statement "that the amount of oxygen combined with the caoutchouc is an index of the amount of deterioration which it has undergone," cannot be applied all round indiscriminately, and must lead to serious errors in cases where the rubber articles have been manufactured with addition of natural resins and gums, between which and the india-rubber resins I have not been able to discover any characteristic difference.

It is clear that the separation of these resins from the insoluble components of india-rubber articles offers very little difficulty, but the same cannot be said with regard to the separation of the india-rubber from india-rubber substitutes; and great credit is due to Henriques for the at once exceedingly simple and satisfactory way he devised to attain this end. I must, however, mention that a process for the same purpose, originated, I believe, by Mr. Boias, was communicated to me some two or three years ago by Mr. Carter Bell. This process consists in treating the finely-ground or cut sample with an ethereal solution of peroxide of hydrogen, whereby the india-rubber is oxidised into a compound easily soluble in alcohol, while any india-rubber substitute present remains unaffected, so that the loss on extraction of the oxidised sample with alcohol represents india-rubber. The residue from this extraction is then heated and the india-rubber substitute distilled off, any mineral matter present remaining behind. I have spent a great deal of time in the attempt to obtain, by the application of this method, the results I was told it yielded, but have been utterly unsuccessful. Solutions of peroxide of hydrogen containing from 5 to 50 volumes of available oxygen proved equally inefficient. Oxidation, indeed, did take place, but it proceeded exceedingly slowly. As a matter of fact, I have not been able to effect complete oxidation by three weeks' treatment with an ethereal solution, containing 32 volumes of available oxygen.\* About 19 per cent. of the total india-rubber present I found to be

\* To give an idea of the exceedingly slowness with which the oxidation proceeds, I may say that after all this time the other still contained 13 volumes of available oxygen, while the greater part of the india-rubber present was still unoxidised.

soluble in alcohol after this time. The alcoholic solution contained not the slightest trace of sulphur, but the percentage of sulphur in the unoxidised part of the sample was found to be very much higher than before; in fact, the total quantity of sulphur present had remained exactly the same. This seems to show either that only the unvulcanised india-rubber present is oxidised, or that at any rate the oxidation is the mere incomplete the higher the degree of vulcanisation of the india-rubber. This observation reveals an important relation between the liability of an india-rubber article to suffer oxidation and its degree of vulcanisation, but it proves at the same time that, for the analysis of india-rubber articles, particularly for the separation of india-rubber from rubber substitute, the above-mentioned method is impracticable.

A complete analysis of an india-rubber article will have to contain the following data:—

1. India-rubber.
2. India-rubber resins.
3. India-rubber substitutes.
4. Free fatty oils, mineral oils, resin oil, resin, paraffin wax, and bituminous bodies.
5. Sulphur of vulcanisation.
6. Sulphur and chlorine in substitute.
7. Free sulphur.
8. Mineral matters.

This enumeration is of course not meant to represent the order in which these items should be estimated; this will largely depend upon the methods employed for the isolation of the various compounds. In any case the estimation of the mineral matters present will for obvious reasons always be the last operations. The other substances occurring in india-rubber articles may be divided into two groups, one of which embraces all those of the above-named compounds which at temperatures not exceeding 100° C. are practically insoluble in all organic solvents, while the second group contains substances which in most of the usual organic solvents are very easily soluble. These two groups therefore comprise respectively:—

A (insoluble).	B (easily soluble).
1. India-rubber.	(6.) India-rubber resins.
2. India-rubber substitute.	(7.) Oils, resins, paraffin wax, &c.
3. Sulphur of vulcanisation and chlorine in combination with rubber.	8.) Free sulphur.
4. Sulphur and chlorine in substitute.	
5. Mineral matters.	

Besides these analytical data, some of the physical properties of the samples may be found of importance in judging their quality. Such properties are the specific gravity, tensile strength, dry heat test at 270° F. for one hour, and moist heat test at 320° F. for three hours. I do not propose to enter upon a discussion of these physical tests, but I may say that they are undoubtedly of very high practical value, enabling one to determine within a few hours whether a given sample comes up to a certain standard or not. On the other hand, however, I may just observe that the results of these tests, while giving a fair idea of what we may call the efficiency of an india-rubber sample, give only a very crude and deceptive notion of its intrinsic quality. For this reason I hold that these physical tests should be supplemented by an analysis, which for ordinary purposes might be sufficient if giving the percentages present of india-rubber, organic bodies other than india-rubber, and mineral matter. I shall show further on that such an analysis can comfortably be made in about half a day.

Having above divided the constituents of india-rubber articles in two groups, according to their solubility in organic solvents, it is a matter of course that we shall begin the analysis by separating a sample to be examined into these two groups. Although a number of experiments on the solubility or insolubility of india-rubber, rubber substitute, and the substances mentioned above in the B group have been published, I thought it advisable to submit that question

to a systematic re-examination, as I believe some of the statements made in regard to this subject to be either misleading or obviously incorrect.

All india-rubber resins are soluble in ethyl alcohol, methyl alcohol, acetone, ether, chloroform, benzene, and bisulphide of carbon. The three last-named solvents will also dissolve unvulcanised india-rubber, which not unfrequently occurs in india-rubber articles, and for this reason they cannot be considered suitable for the intended separation. Ethyl ether can scarcely be called a solvent for india-rubber, although it seems to a slight extent capable of dissolving the non-resinous constituents of some of the inferior qualities of india-rubber. It may therefore be advisable to reject even ether as a solvent for our purpose. Mixtures of alcohol and ether, in which the volume of the latter does not exceed twice the volume of the alcohol, are quite incapable to dissolve any india-rubber, but this mixture has the drawback of not being suitable for extraction in a Soxhlet tube, owing to its boiling point not being constant. A mixture of benzene and methyl alcohol (1 : 2), which I recommended some time ago for the extraction of oily and resinous substances from india-rubber, answers very well, and has the great advantage of a constant boiling point (56° C.). I have, however, abandoned the use of this solvent in favour of acetone, which is an excellent solvent for all the substances here in question, but has not the slightest action upon india-rubber and vulcanised oils. Acetone has the further advantage, which will often be found very useful in the analysis of oily and resinous matters, to be miscible in all proportions with water, as also with all of the usual organic solvents. But whichever of these solvents be employed for the separation of the constituents of an india-rubber sample in the two above-mentioned groups, it is most important to have the sample in the finest possible state of sub-division. Cutting the sample is a very wearisome and never particularly satisfactory process, and I prefer to pass it several times between steel rollers revolving in contact. The sample is thereby reduced into a mass of exceedingly fine and easily permeable flakes.

The behaviour of rubber substitutes against solvents was examined by Holde (this Journal, 1893, 469), who found a sample, prepared by heating on the water-bath a mixture of 4 grms. of linseed oil with 4 grms. of chloride of sulphur and 4 cc. of carbon bisulphide, to be quite insoluble in ether. Unfortunately the idea does not appear to have struck that author, that the rubber substitute produced in this extraordinary manner might possibly be different from the commercial article. The fact that there exists the greatest possible difference between the two, renders his elaborate series of experiments with this compound quite valueless, and his conclusions based upon them more or less erroneous. I have analysed upwards of 400 samples of india-rubber substitute and never observed less than 6 per cent. of ethereal extract, but often as much as 11 per cent. Holde further proposes to estimate fatty oils contained in manufactured rubber by extracting 1 grm. of the finely-cut sample with 60 cc. of ether-alcohol (2 : 1) upon a filter, evaporating the filtrate, and drying and weighing the residue. Of the percentage of extract thus obtained he deducts, by way of a correction, 5 per cent., having observed that a number of india-rubber articles, which he merely supposes to be pure, give 5 per cent. of ether extract. The correctness of this method he attempts to demonstrate by impregnating rubber filings with weighed quantities of colza or cotton-seed oil, subsequently extracting them in the above-mentioned manner. Of course he obtains thus tolerably concordant results, but it does not occur to him that extracting the total quantity of oil added to filings of vulcanised india-rubber from the latter is one thing, and extracting the oil added to india-rubber during the process of manufacture another. Any fatty oils entering into the rubber mixture before vulcanisation are bound to undergo an alteration, in part at least, during vulcanisation; in fact, they are more or less converted into substances of the nature of a rubber substitute, which is no longer soluble in ether. Very questionable also is the admissibility of the above-mentioned correction of 5 per cent. which Holde applies to his gross results. Technically pure Pará rubber contains from 0.5 to 2 per cent. of resin. If this rubber is vulcanised by the cold process the extract it yields is not in

excess of the quantity of resin originally present (not taking into account any free sulphur which may be contained in the extract), provided the boiling point of any solvents employed does not exceed 110° C. If, on the other hand, the rubber be vulcanised by the hot process it may yield from 4 to 8 per cent. of extract according to the time and temperature allowed for vulcanisation, both of which depend upon the percentage of sulphur used and also upon the presence or absence of sulphur carriers in the mixture.

The addition of fatty oils to india-rubber mixtures is very little practised nowadays, mineral or resin oils being used

instead. The estimation of these unsaponifiable oils in extracts obtained from india-rubber articles offers little difficulties, but a single extraction of the sample with ether-alcohol is utterly insufficient to remove the whole of these oils. In many cases I found it necessary, and in all cases advisable, to repeat the extraction 10 times in order to completely exhaust the samples. This of course is easily done in a Soxhlet tube, and I prefer, as I stated before, to use acetone as the solvent. These points are well illustrated by the following series of experiments:—

	1st.	2nd.	3rd.	4th.	5th.	10th.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
I. White substitute .....	4.82	6.58	8.16	8.73	8.91	8.98
II. Black substitute .....	12.22	15.01	16.82	16.75	20.55	20.74

XII. Tobacco pouch, best quality (Messrs. D. Moseley and Sons, Manchester).	4.22	4.92	5.52	5.97	6.58	6.66

These figures unquestionably prove the insufficiency of Holde's above-mentioned method of extraction; further, the possibility of effecting complete extraction by adopting the means proposed above; and lastly, the impossibility of detecting by extraction the amount of fatty oils added to india-rubber during the process of manufacture.

The estimation of the constituents of the extracts will have to be carried out essentially by the well-known methods of separating fatty oils from mineral oils and resins. I must, however, point out that the results of this separation will not admit of any definite interpretation respecting the nature of the india-rubber contained in the sample, or regarding the quantity of fatty oils or resin employed in the manufacture of the article. The reasons for this are obvious. There exists no fundamental difference between the resins contained in india-rubber and the other natural resins, both being genetically closely related to the terpenes or polyterpenes. For this reason the smell of burning india-rubber resin is also identical with that of the other resins. The estimation of any fatty oils added during manufacture is absolutely impossible, if at the same time india-rubber substitutes have been employed. Even the amount of added unsaponifiable matters can only approximately be estimated, owing to the fact that the india-rubber resins as well as the other natural resins are mixtures of saponifiable and unsaponifiable substances in variable proportions. The estimation of the free and combined sulphur in these extracts offers, however, little difficulty, but in all cases where the estimation of the free sulphur offers no

interest, I prefer to estimate simply the total sulphur in the extract, as this figure is sometimes wanted for the estimation of the sulphur of vulcanisation, which in my opinion is one of the most important data of a complete analysis of an india-rubber article. If, however, the separation of the constituents of the acetone, is in most cases a matter of subordinate interest, the total extract nevertheless is a very useful figure, as its amount may safely be taken to be inversely proportionate to the quality of the total organic constituents of an india-rubber sample.

Lately a controversy on a point of some importance with regard to this extraction question has arisen between Henriques and myself. I stated in a former paper (*Zeitschr. f. angew. Chem.* 1893 [21], 22; see abstract this Journal, 1894, 33) that a mixture of one vol. of benzene and two vols. of methyl alcohol had no solvent action whatever upon india-rubber or vulcanised india-rubber. This statement Henriques opposes on the strength of an experiment with a sample of vulcanised Pará rubber, from which, by means of that solvent, he extracted 2.41 per cent. of substance other than sulphur. I have not the least doubt regarding the correctness of Henriques' figure, but what I certainly doubt is that these 2.41 per cent. he extracted consist of either india-rubber or vulcanised india rubber. Part of his extract is certain to consist of india-rubber resin. The remainder is a compound of a resinous nature and containing sulphur. Even when using india-rubber freed from every trace of india-rubber resin, hot vulcanisation with sulphur always results in the formation of a certain quantity of this "resin

of vulcanisation" as we may term it. If the vulcanisation process be well conducted the quantity of this resin formed appears to be very small, seldom exceeding one per cent. But whenever vulcanisation is effected at too high a temperature, or if the treatment, at what might otherwise be a suitable temperature, has been too prolonged, correspondingly large quantities of this resin are formed.

The most important part of the analysis of an india-rubber article, no doubt, is the estimation of the substances above enumerated in group A. The merit to have shown a thoroughly satisfactory way at least to separate india-rubber from india-rubber substitute, is entirely due to Henriques. His method, which consists in the treatment of the sample with alcoholic caustic potash or soda (this Journal, 1893, 467), requires no further comment. With regard to the quantity of substitute found by this method, it is evident that it stands in inverse ratio to the commercial value of the sample, but to ascribe to india-rubber substitutes, as has been done lately (Chem. Zeit. 1894, 310, 329; Lobry de Bruyn and van Leent), a general deleterious influence upon the stability of india-rubber goods is certainly not warranted by facts. The fact that improperly prepared india-rubber substitutes are sometimes the cause of the premature and spontaneous decomposition, can scarcely be considered a valid reason for the wholesale condemnation of all india-rubber substitutes. In numerous cases the manufacture of an india-rubber article from pure india-rubber would amount to a waste of material, which the consumer would be loth to pay for. Of course the cost price of an article can be reduced by addition of mineral matters to the india-rubber, as well as by addition of substitute, but it would be a great mistake to presume that, generally speaking, mineral substances can replace the india-rubber substitute in india-rubber articles. Such an indiscriminate substitution would lead to considerable modifications of the physical properties, especially of the tensile strength (co-efficient of elasticity) and of the resistance against disintegration by friction of the india-rubber articles, so as to render them in some cases quite unfit for technical uses. I am speaking from experience in saying that the use of properly prepared india-rubber substitutes does not involve any danger whatever as regards the stability and serviceability of india-rubber articles, and the prohibition of their use would be about as reasonable as the prohibition of wood pulp or esparto in the manufacture of low and medium class papers.

If a sample of an india-rubber article does not contain any mineral matter the analysis would be practically concluded after the above-mentioned extraction of the india-rubber substitute by means of alcoholic caustic potash, according to Henriques' method. The part of the sample remaining undissolved in this treatment would then simply represent pure vulcanised or partly vulcanised india-rubber. But in many cases an india-rubber sample may contain small quantities of inorganic colouring matters, the presence of which it is sometimes difficult to discover merely by the look of the sample. For this reason I consider it advisable always to dissolve this residual india-rubber, when the presence of the least quantity of mineral matter will readily be detected. For the solution of the india-rubber, vulcanised and unvulcanised, Henriques proposes to boil the residue remaining after the extraction of the rubber substitute, with that fraction of petroleum boiling from 140° to 250° C. This part of Henriques' method I consider very defective, as according to my experience, strongly vulcanised india-rubber will never dissolve in this solvent. Even in cases where complete solution is eventually obtained the time required is often excessively long. I have never been able to dissolve any sample in less than 10 hours. The solutions obtained, as against solutions effected by heating with boiling oil of turpentine, possess the advantage not to resinify on the filter, but their filtration is generally a very tedious and difficult operation. Evolution of sulphuretted hydrogen does not occur in this solution process, provided all free sulphur has been previously extracted, which is always the case if the first extraction is executed with acetone in the manner described above. The complete extraction of all free sulphur is of course of the greatest importance if it should be desired to estimate

the sulphur of vulcanisation in the india-rubber, a figure to which I attach great importance.

The unsatisfactory nature of Henriques' solvent for india-rubber induced me to examine more particularly this point of the analysis of india-rubber. Very obvious is the assumption that the employment of solvents possessing a higher boiling point might lead to more satisfactory results. This, however, was found not to be the case, neither vaseline nor paraffin showing themselves any superior to petroleum as used by Henriques. Indeed I invariably observed the appearance of black, charred-looking masses, as soon as the temperature of the solvent exceeded 230° C. This observation is perhaps not very surprising if we remember that petroleum hydrocarbons of the paraffin and olefin series are rather poor solvents even for unvulcanised india-rubber, forming with it solutions which are peculiarly devoid of the quality known as "body." By considerably diluting these solutions liquids are obtained which cannot be filtered through paper, the filtrate simply consisting of a solution of the india-rubber resin. I believe indeed that these so-called solutions of india-rubber in petroleum hydrocarbons are merely liquid jellies. This makes it perfectly clear that the solution of vulcanised india-rubber in this solvent is not to be thought of. If, therefore, by the application of Henriques' method a solution is obtained, it must evidently be a solution of the products of the decomposition of india-rubber at the temperature of the boiling solvent. The decomposition of unvulcanised india-rubber begins already at 160° C., that of vulcanised india-rubber between from 190° to 220° C., according to the degree of vulcanisation. The products of this decomposition are terpenes or polyterpenes, which are very subject to further polymerisation, thus forming black resinous substances, which, however, are exceedingly difficultly soluble in petroleum hydrocarbons. These polymerisation products will be produced in increasing quantities the higher the temperature at which decomposition begins, or, in other words, the higher the degree of vulcanisation of the india-rubber. What we require therefore is a solvent which will easily dissolve unvulcanised india-rubber as well as the decomposition products and their polymers of vulcanised india-rubber. The boiling point of the solvent should be high enough to induce the decomposition even of strongly vulcanised india-rubber, accordingly it should be above 200° C., but not exceed 210° C. Of the easily accessible and cheap solvents nitrobenzene answers all these requirements, it being an excellent solvent for india-rubber, while its boiling point (208° C.) could not be more suitable. The behaviour of this solvent against vulcanised india-rubber is most surprising. In the cold, quicker on heating the vulcanised india-rubber immersed into this solvent swells considerably, without solution taking place. On prolonged heating the india-rubber becomes transparent, and as soon as the boiling point of the solvent is reached solution ensues within a few seconds. Any mineral matter present quickly settles out, the supernatant solution being perfectly clear and only slightly darker in colour. Henriques' boiling petroleum has no action upon india-rubber substitute, while the boiling nitrobenzene dissolves these compounds as readily and completely as it dissolves vulcanised rubber, so that this solvent not only places at our disposal an efficient means for the estimation of the india-rubber, and, as I shall show later on, of the sulphur of vulcanisation, but at the same time also for the ready estimation of the quantity, and, what is quite as important, of the nature of the mineral matters present. Only the presence of red lead escapes direct detection in this process, it being very quickly reduced to oxide of lead by the boiling solution. If, therefore, the presence of red lead is suspected in a sample, a special test has to be used for its detection. For this purpose I impregnate a few grammes of the well-ground sample with a saturated solution of anhydrous aluminium chloride in pure ether and subsequently heat for two hours in an air bath at 126° C. In the presence of small quantities only of red lead the sample becomes very hard and brittle, while in the presence of larger quantities the sample is converted into a gritty dust and frequently exhibits a strong smell of chlorine. Addition of red lead to india-rubber mixings is, however, a thing very uncommon at present, most manufacturers

knowing full well the inevitable fatal influence of this compound upon india-rubber.

In carrying out this separation of the india-rubber from the mineral matters, 3 grms. of the sample, after extraction with acetone and subsequently with alcoholic potash, are placed in a flask together with about 150 cc. of nitrobenzene. This flask is attached to a vertical glass tube, which serves as a reflux condenser. Solution of the india-rubber ensues within a few minutes after the boiling point of the liquid (208° C.) has been reached. In order, however, to make quite sure of the completeness of the solution, I continue the boiling for about half an hour. This has also the advantage of rendering the solution much easier to filtrate, from which fact we may infer that on boiling the molecule of the india-rubber gradually breaks up into smaller molecules of easier soluble substances. What these are I do not know, but I intend to follow up this reaction by a special research. The solution obtained as described is eventually filtrated, the flask and filter residue being washed with warm nitrobenzene. The weight of the dissolved india-rubber including the sulphur of vulcanisation is then found by weighing the dry residue on the filter, consisting of mineral matter only.

In most cases the figures obtained by means of this process represent the quantities of vulcanised india-rubber and mineral matter actually present. There are, however, certain admixtures employed in the manufacture of india-rubber articles which may considerably detract from the value of these analytical figures. This is especially the case when the samples contain so-called "recovered rubber" or "devulcanised rubber," i.e., old rubber articles which, either by treatment with certain oils, or simply by grinding, have been brought in such a form and state as to be again suitable for incorporation into fresh rubber mixings. The proportion in which fresh rubber and such recovered rubber has been employed in the production of a new article cannot be detected by our present analytical methods, and this is, no doubt, a great defect, as the use of this recovered rubber, which, in many cases, merely consists of ground-up old rubber articles, is very much on the increase.

Peculiar difficulties arise if an india-rubber article contains starchy matters, an addition not unfrequently practised. In the process of vulcanisation the starch does not seem to suffer any alteration, which is not very surprising, considering the temperature at which the vulcanisation process is carried out. The presence of starch can, therefore, be detected qualitatively by means of the iodine test, provided the articles be light in colour. In darkly coloured articles the reaction is generally very doubtful. The quantitative estimation of this starch offers no difficulty, and can be effected without any alteration in the course of analysis as above mentioned. Several experiments showed that ordinary air-dry starch, containing about 18 per cent. of water, is not destroyed by boiling in nitrobenzene.

7.597 grms. of farina, containing 18.2 per cent. of water, were boiled for one hour with 100 cc. of nitrobenzene. No discoloration was observable. The contents of the flask were subsequently filtered, flask and filter being washed with ether; the filter residue was eventually dried at 110° C., and was then found to weigh 6.204 grms., which with the 18.2 per cent. of water contained in the air-dry starch would amount to 7.586 grms. Thus we see that this treatment with nitrobenzene, although subjecting the starch to the very high temperature of 208° C., causes no loss in weight through decomposition. On closer examination of the starch thus recovered, it was, however, found that an alteration had taken place, resulting in the conversion of the starch into soluble starch and very little dextrin. We are, therefore, in a position to estimate very accurately any starch contained in an india-rubber article, by dissolving the sample freed, in the manner before described, from extractive matter and india-rubber substitute, in boiling nitrobenzene. The starch, together with any inorganic substances present, subsequently remains on the filter. The separation of starch and mineral matter is effected simply by treatment of the filter residue with boiling water, the starch being estimated by evaporating the filtrate, drying the residue at 110° C., and weighing. The quantity of starch thus found is, of course, not the actual quantity of commercial starch added to the rubber mixing. This quantity is obtained by increasing the figure by the amount of moisture contained in commercial starch, and which, as I stated before, amounts to about 18 per cent.

Some further difficulty arises if the sample under examination contains asphaltum, the presence of which is frequently indicated by a high percentage of total sulphur, owing to the asphaltum often being employed in the form of a sulphinated product, containing as much as 20 or 22 per cent. of sulphur. Henriques suggested to estimate it by treating the sample, which of course must be free from extractive matters and substitutes, with cold nitrobenzene, in which the asphaltum is readily soluble. This process answers very well. If, however, instead of the natural asphaltum, artificial asphaltum, prepared from gas-tar and pitch, has been employed, the results obtained by this method are somewhat too low, owing to the considerable quantities of finely-divided carbonaceous matter contained in the artificial product. This carbonaceous matter is of course met with later on, together with the mineral matters.

I have prepared some samples on a large scale, in order to test the accuracy which can be attained in the analysis of india-rubber goods containing the above-mentioned components. The india-rubber used for this purpose was Assam, containing 11.3 per cent. of resin. I preferred to experiment with such a medium quality, which shows much better than the high-class rubbers the influence of the india-rubber resins upon the analytical data obtained:—

	I.		II.		III.		IV.	
	Mixed.	Found.	Mixed.	Found.	Mixed.	Found.	Mixed.	Found.
Assam (with 11.3 per cent. of resin) ..	55	46.61	55	47.37	55	47.01	55	47.63
Resin.....	..	8.21	..	7.49	..	7.74	..	7.09
Substitute, white, refined (9.27 per cent. S).	15	15.3	15	15.05	15	14.96	15	14.78
Lead oxide.....	10	11.93	10	9.91	..	..	..	..
White lead. ....	10	7.74	..	..	..	..	..	..
Barium sulphate.....	5	4.88	..	..	..	..	..	..
Vermilion .....	..	..	5	5.02	..	..	..	..
Antimony sulphide .....	..	..	10	10.12	5	4.94	10	9.92
Asphaltum (18.1 per cent. S) .....	..	..	..	..	..	..	15	14.19
Farina (18.01 per cent. H <sub>2</sub> O).....	..	..	..	..	20	16.02 (= 16.53)	..	..
Sulphur (added) .....	5	4.86	5	4.89	5	4.87	5	7.65
Temperature of vulcanisation .....	134° C.		125° C.		125° C.		125° C.	

These results show that the quantity of resin extracted is, without exception, rather higher than corresponds to the proportion of resin contained in india-rubber. The reason of this, as I pointed out before, is to be found in the formation of resinous matters from the india-rubber during vulcanisation, and I may mention that the quantities of such resins formed are smaller if vulcanisation is effected in the presence of energetic sulphur carriers, such as antimony sulphide. White lead seems to suffer partial decomposition into lead oxide and carbonic acid, which accounts for the too high figure for lead oxide and the too low figure for white lead obtained above. The fact that in the second of the above samples the percentage of both vermilion and antimony sulphide are slightly too high is probably due to the original mixture not being perfectly homogeneous. The figure for starch refers to the substance dried at 110° C.; adding to it the proportionate amount of water contained in air-dry farina, the result is seen to be most satisfactory. The sulphur was obtained by estimating the total sulphur and deducting from this the amount of sulphur contained in the india-rubber substitute.

Lately Henriques suggested estimating the free carbon (lampblack) in india-rubber articles, containing, besides india-rubber oils, rubber substitute and asphaltum only, by first separating from the rubber all these soluble constituents by the processes above referred to, and determining by combustion, the proportion of carbon and hydrogen contained in the remaining india-rubber. This suggestion is based upon the fact that all reliable analyses of india-rubber show the relation of C : H = 10 : 16. Any lampblack mixed with the india-rubber will of course lead to a higher figure for carbon, the percentage of which could then be arrived at by simple calculation. This suggestion may be workable, but I certainly prefer to estimate the free carbon by dissolving the india-rubber in nitrobenzene, filtering the solution through a weighed filter, washing with ether, and drying.

The above-described methods enable us to make a complete analysis of practically any india rubber article with regard to the percentage of india-rubber, and of all the admixtures, other than sulphur, usually employed in the manufacture of these goods. The following is a short recapitulation of the various stages of the process :—

- (1.) Extraction with acetone.
  - (a.) Fatty acids and oils in extract.
  - (b.) Saponifiable resins in extract.
  - (c.) Unsaponifiable matters in extract.
- (2.) Extraction of rubber substitutes with alcoholic potash (Henriques' process).
- (3.) Extraction of asphaltum with cold nitrobenzene (Henriques' process).
- (4.) Estimation of india-rubber by means of boiling nitrobenzene.
- (5.) Estimation of starch.
- (6.) Estimation of mineral and carbonaceous matters.

The figures for 1, 3, 5, and 6, I prefer to determine by weighing the extracts direct; 2 and 3 are best determined from the loss of weight of the substance operated upon. It is possible to estimate the quantity of india-rubber substitute present by direct weighing, but no greater accuracy of results is gained thereby. To weigh the quantity of the india-rubber dissolved in the nitrobenzene direct, I have not been able yet to do, as in distilling off the nitrobenzene, volatile decomposition products of the india-rubber escape in considerable quantity.

The estimation of the sulphur contained in india-rubber articles is one of the most important points of their analysis. The various forms in which the sulphur may occur in an india-rubber article differ very much in their influence upon the quality and durability of it, and for this reason the total sulphur, without the knowledge of the various items it is composed of, is of very little interest. The total sulphur of india-rubber articles in the first instance divides itself under three heads :—

- (a.) Free sulphur.
- (b.) Sulphur in organic compounds.
- (c.) Sulphur in inorganic compounds.

The quantity of free sulphur contained in a sample is an item of some importance, as it is well-known that a high percentage of free sulphur invariably proves detrimental to the durability of india-rubber goods—in fact, is one of the most common causes of their decay.

Even more important than the free sulphur is the "sulphur in organic compounds," as it includes the sulphur of vulcanisation. For this very reason, however, the separation of the sulphur in organic compounds into its various forms becomes further necessary. Of chief importance is the estimation of the sulphur of vulcanisation, while the sulphur contained in india-rubber substitutes or asphaltum, which may be present, is generally of subordinate interest only. Natural asphaltum contains about 10 per cent. of sulphur, but the asphaltum used in the manufacture of india-rubber goods sometimes contains as much as 20 per cent. of sulphur, so that a sample containing this admixture often shows a surprisingly high percentage of total sulphur and of sulphur in organic combination.

The sulphur in inorganic compounds is of minor interest. It is estimated in the final residue remaining after the solution of the india-rubber by the well-known methods for the analysis of inorganic sulphides and sulphates. The sulphates contained in the inorganic residue represent always deliberate admixtures. Sulphites are present whenever thio-sulphates have been added in the mixing of the rubber, although small quantities of them may also be formed by the action of the free sulphur upon litharge or zinc oxide at the temperature of the vulcanisation. Sulphides either have been added as such (antimony sulphide, zinc sulphide, vermilion), or their presence is due to the action of the free sulphur upon the before-mentioned metallic oxides. All sulphides, especially those of antimony and lead, play in the vulcanising process the part of sulphur carriers.

From the above it follows that the complete analysis of an india-rubber article requires the estimation of the sulphur in the following states :—

- |                 |  |
|-----------------|--|
| Total sulphur : | a. Free sulphur.                       |
|                 | b. Sulphur in organic compounds.       |

|                 | c. Sulphur in inorganic compounds.     |

Of the various methods suggested for the estimation of the total sulphur and of the sulphur in organic combination in manufactured india-rubber, only the well-known method of Carius and the one devised by Henriques can be recommended, and I prefer the latter as being for our purposes at once the most reliable as well as the most expeditious.

As regards the analytical import of these various forms of sulphur, I have already mentioned the well-known fact that the amount of free sulphur present in a sample often affords an explanation of the bad-keeping qualities of manufactured rubber. Of course, I do not mean to say that the apparently spontaneous decay of such goods is invariably attributable to any free sulphur which may be present, although the appearance on the surface of india-rubber goods of a greyish efflorescence can always unhesitatingly be put down as due to free sulphur. It is, however, remarkable that this efflorescence does not, as has been generally assumed, consist of pure sulphur, but invariably also contains ammonia sulphate, the quantity of which increases considerably with the age of the efflorescence. The proportion of ammonia sulphate observable in these cases is particularly great in goods which have become hard and brittle owing to excess of sulphur. It occurs to me that this fact furnishes an explanation of the real cause of the danger which is involved in the presence of free sulphur in india-rubber. It is a daily observation that substances in close contact with india-rubber undergoing oxidation, also favour the oxidation of the india-rubber itself, just like the oxides of manganese and copper which, acting as powerful oxygen carriers, are justly held to be the greatest enemies of india-rubber. This action of manganese which I first observed some three years ago is not generally known yet, the perniciousness of copper was first observed and well

demonstrated by Mr. Thomson. Fatty oils have no effect upon india-rubber, provided access of air to the latter be prevented, but as soon as on admission of the air the oil becomes rancid, the decomposition of the india-rubber also begins. Evidently for this reason the quick-drying oils, and those of the non-drying oils which easily become rancid, are so dangerous to india-rubber. Now it has been known for a long time that sulphur in a very fine state of sub-division rapidly undergoes oxidation and upon this fact, I consider, rests the detrimental action of free sulphur upon india-rubber. On the other hand, however, this contention involves the conclusion that this danger of free sulphur only exists where it is present in india-rubber in such a quantity that it exhibits a tendency to migrate to the surface of the goods. This conclusion well agrees with observed facts, but it is nevertheless impossible to state in definite figures at which percentage free sulphur begins to be dangerous. This is, no doubt, due to the fact that a number of substances which may occur in india-rubber articles highly favour the above-mentioned migration of the sulphur by dissolving it. Substances of this kind are the fatty oils, mineral oils, resin oils, and particularly the heavy portions of the india-rubber solvents. Thus it may happen that a quantity of free sulphur which in one case shows no effect whatever, may in another case be responsible for the decay of an india-rubber article.

The estimation of the free sulphur is done in the extract obtained on the extraction of the sample with acetone, which solvent readily extracts the finely subdivided sulphur. It is, however, important to state that not all the sulphur contained in this extract is free sulphur, as whenever the extracted sample contains rubber substitutes, the extract will also contain sulphides of fatty acids, and it further contains sulphides produced by the action of the free sulphur upon the resins, which are always to be found in india-rubber. For this reason the amount of the total sulphur in the extract is generally very much in excess of the free sulphur which is really present. The estimation of the free sulphur I carry out by adding to the above-mentioned extract 20 cc. of a solution of pure sodium sulphide and caustic soda ( $5\text{NaOH} : 15\text{Na}_2\text{S} : 100\text{H}_2\text{O}$ ), and heating this mixture on the waterbath for about an hour. Even in the presence of a large proportion of unsaponifiable matters the whole of the extract dissolves. I then dilute with warm water and precipitate the fatty acids contained in this solution by adding a slight excess of a solution of barium hydrate. The whole is then filtered, the filter well washed, the filtrate subsequently made up to 300 cc., and the sulphur estimated in an aliquot part of it. This method is the only one by which concordant results could be obtained. The following analyses were made by it:—

I. Steam hose: manufactured from 60 per cent. of india-rubber (Madagascar with 8.1 per cent. of resin), 36 per cent. of brown substitute (11.4 per cent. solution in acetone), 4 per cent. of sulphur.

Total extract: 10.9 per cent., containing 1.65 per cent. of total sulphur.\*

Saponified with 20 cc. of sodium sulphide containing 6.154 grms. of S in 100 cc.

Filtrate after saponification made up to 300 cc., 50 cc. of it oxidized with  $\text{H}_2\text{O}_2$ , then precipitated with barium chloride.

Found: 2.1008 grms. of  $\text{BaSO}_4 = 0.2885$  grms. S = 1.731 grms. in 300 cc.

The 20 cc. of sodium-sulphide used for saponification contain 1.2308 grms. of S, consequently we have free sulphur in the extract:  $1.7310 - 1.2308 = 0.5002$ , or free sulphur in the sample analysed: 0.5 per cent. Repeated estimations yielded 0.48, 0.51, 0.48 per cent. respectively.

The examination of the substitute employed in the manufacture of the above sample yielded 11.4 per cent. of an extract containing 5.3 per cent. of sulphur. Consequently only 0.2173 grms. of the total sulphur found in the extract can be derived from the rubber substitute. This quantity, together with the free sulphur, is still by

0.93 per cent. short of the observed quantity of total sulphur in the extract. This 0.93 per cent. of course represents part of the 4 per cent. of sulphur employed in the manufacture of the sample, and it must be contained in the extract in the form of a highly sulfonated resin of vulcanisation. That this is so is also clearly indicated by the total quantity of extract obtained from the sample, which is rather higher than the aggregate of the extractive matter contained in the components of the sample.

II. 60 parts of india-rubber (Madagascar), 40 parts of brown substitute, 9.6 parts (10 per cent.) of sulphur.

Total extract: 14.97 per cent., containing 7.82 per cent. of total sulphur.\*

Found: Free sulphur 5.66 per cent.

Sulphur from substitute (calculated) 0.222 per cent.

Sulphur in resin of vulcanisation 1.94 per cent.

In accordance with what I have previously stated regarding the formation of resins of vulcanisation this analysis shows that their proportion increases with the excess of sulphur employed for the vulcanisation.

The estimation of the sulphur in organic compounds we have above divided under four heads. Of these the first combined sulphur in the acetone extract—is readily obtained by deducting from the total sulphur in the extract, the free sulphur. Articles manufactured with brown rubber substitute may contain a very considerable quantity of combined sulphur in the acetone extract.

The "sulphur in substitute," i.e., in that part of it which is insoluble in acetone, is ascertained according to Henriques' method in the extract obtained on treating the sample with alcoholic potash. This portion of the total sulphur is, however, of little interest unless it be desired to obtain some information regarding the nature of the substitute. For details on this point I refer to Henriques' paper on this subject (this Journal, 1893, 167).

Of considerable importance is the estimation of the sulphur of vulcanisation, which is, no doubt, of the greatest influence upon the serviceability and the durability of an india-rubber article. The question as to the quantity of sulphur combining with india-rubber has been repeatedly discussed, but is very far from being settled. Thus, I believe, is due to the fact that in these discussions the vital point of this question, i.e., the chemical nature of the sulphide or sulphides as which vulcanised india-rubber must be considered, has been altogether neglected. Terry states that by repeated treatment with solution of caustic soda he has been able to reduce the sulphur of vulcanised india-rubber to 0.6 per cent. This I do not doubt, but I certainly do not believe that this sample would be as well vulcanised with 0.6 per cent. sulphur as say with 2 or 2.5 per cent. Lobry de Bruyn and van Leent, strange to say, confirm Terry's statement, although the sulphur minima they observed are from three to four times as high as Terry's figure. Although we know with tolerable certainty that india-rubber is not a homogenous hydrocarbon, we may on the other hand safely assume that the molecular weights of the various hydrocarbons composing it are very little different. Indeed, the chemical behaviour of india-rubber suggests that they are merely isomeric. Still less doubtful is the fact that the vulcanisation of india-rubber, as I have shown in a previous paper, consists in the formation of sulphides or disulphides of definite composition. If, therefore, 0.6 per cent. of sulphur should be considered as the minimum of sulphur required for the complete vulcanisation of india-rubber, we are bound to accept its molecular weight as 5,300, which leads to the formula  $(\text{C}_{10}\text{H}_{16})_{95}$  or  $\text{C}_{950}\text{H}_{1520}$ . This formula will surely find its champion to defend it. Even with the assumption that the sulphur in the vulcanised india-rubber exists in the form of a double atom, as is indeed the case in those goods which have been vulcanised with chloride of sulphur, the above formula would be  $\text{C}_{475}\text{H}_{760}$ , which still is certainly by far too large. Applying the same calculation to de Bruyn and van Leent's figures, a molecular weight of  $\text{C}_{1100}\text{H}_{1760}$  appears as the most probable, and I take it as very significant that this is the same which I deduced for india-rubber from the investigation of its chlorosulphides.

\* Calculated upon the original weight of the sample extracted.

\* Calculated upon the original weight of the sample extracted.

It is certainly a mistake to assume that india-rubber will combine with one definite quantity of sulphur only to form vulcanised rubber. There is no doubt that the vulcanisation of india-rubber with sulphur will, on closer examination, be found to be analogous to the vulcanisation with chloride of sulphur, and that starting from a minimum, the sulphur of vulcanisation can be increased until all the available affinities of the india-rubber are saturated and products obtained which probably form the bulk of what is technically known as ebouite, a compound which certainly contains not less than about 20 per cent. of sulphur of vulcanisation. I have analysed a very great number of flexible vulcanised india-rubber goods and found them to contain from 1·7 to 8 per cent. of sulphur of vulcanisation, but all these samples containing less than 2 per cent. of combined sulphur, showed on fresh cuts unmistakable signs of tackiness which increased very much on heating them at temperatures not exceeding 100° C. I have not seen yet a thoroughly sound specimen of vulcanised india rubber containing less than 2·2 per cent. of sulphur. With an increasing percentage of sulphur of vulcanisation the tenacity of the articles increases very much. Goods containing above 5 per cent. of sulphur possess an enormous tensile strength which, however, appears to be developed at the expense of their elasticity.

In order to estimate the sulphur of vulcanisation, it is of course absolutely necessary first to remove every trace of free sulphur. I stated above that extraction with acetone answers very well for this purpose. I am well aware that the usual way to free vulcanised india-rubber from uncombined sulphur is to boil the sample repeatedly with solutions of the caustic alkalis. But I consider this method to be quite inadmissible as the alkaline sulphides which of course are formed in the first instance possess the property of reducing disulphides into monosulphides. This reaction may be responsible for the very low percentage of sulphur of vulcanisation observed by Terry. Of course, the possibility to prepare vulcanised india-rubber containing only 0·6 per cent. of combined sulphur cannot be denied, but I maintain that in such a product only part of the india-rubber can be vulcanised. But since it is an acknowledged fact that with an increasing percentage of combined sulphur the chemical and physical stability also increases, we must demand of a sound india-rubber article, that it should contain no unvulcanised india-rubber. This is only possible where there are at least 2 per cent. of combined sulphur. In many cases, as for articles which have to stand high pressure steam or high temperatures, a still larger proportion of sulphur will be necessary.

In every case the sulphur of vulcanisation should be estimated direct. For this purpose the solution of the india-rubber in nitrobenzene, is distilled under reduced pressure. The flask containing the non-volatile residue consisting of a treacly mass is then dried at 140° C. and subsequently oxidized with fuming nitric acid. The whole of the residue becomes eventually dissolved and the solution is then transferred to a platinum dish, the flask being rinsed with warm nitric acid. After evaporating the solution on the water bath, the residue is fused with carbonate of soda, the melt dissolved in water oxidized with bromine, acidulated, and the sulphuric acid precipitated with barium chloride. The estimation of the sulphur contained in the asphaltum, which is sometimes present, is performed in a similar manner in the solution of the asphaltum in cold nitrobenzene. The sulphur present in the form of inorganic compounds is estimated in the ultimate residue remaining behind after the solution of the india-rubber, by the well-known methods for the estimation of the sulphur in inorganic sulphides and sulphates.

The above discussed methods enable us to detect and estimate in india-rubber articles the following components:

- I. Fatty oils, mineral oils, resins, paraffin wax.
  - (a.) Free sulphur.
  - (b.) Sulphur in organic combination.
- II. India-rubber substitutes.
  - (a.) Sulphur in substitute.
- III. Asphaltum.
  - (a.) Sulphur in asphaltum.
- IV. India-rubber.
  - (a.) Sulphur of vulcanisation.
- V. Starch.
- VI. Mineral matters, free carbon (lampblack).
  - (a.) Sulphur in inorganic compounds.

In most cases such a detailed analysis is not called for, and the estimation of the acetone extract, rubber substitute, india-rubber and mineral matter, will answer for most purposes. The results obtained are remarkably accurate. Nevertheless, it will be found that even the most complete analysis in some cases does not give the desired information. This most often happens when the article to be analysed has undergone some deleterious change, the cause of which the analysis is expected to disclose. That excess of fatty oils, copper oxide and manganese oxide may cause such a change is known well enough, but often enough this "decomposition" takes place in the absence of those dangerous metallic oxides or oils. In such cases the analysis of these goods is apt to be disappointing, as it

enables us to form an opinion neither of the cause nor of the amount of the decomposition which has taken place. But I believe that this is due not so much to the imperfectness of our analytical methods, than rather to the incompleteness of our knowledge of the decomposition products of india-rubber under the influence of various agents. What is required is the analysis of a great number of decomposed articles, the original composition as well as the cause of the decomposition of which is known. Such analyses will show the effect of this decomposition upon the various components of india-rubber articles, they will also enable us to detect and isolate its products and thus we may hope to be able eventually to pronounce with certainty upon the cause of such a decomposition from the results of the analysis. At present this is, generally speaking, impossible. Anyone who doubts this has only to peruse the scientific evidence produced in the law courts in those rather frequent cases where india-rubber manufacturer and cloth manufacturer attempt to fix one upon the other the responsibility for the decay of water-proof cloth.

The course to be followed in the analysis of india-rubber goods can be indicated in the manner shown on preceding page.

#### DISCUSSION.

Mr. HEYS said he should like to correct Dr. Weber's statement in reference to Hutchinson's method. He stated that it was obtained from Mr. Bolas—that it was very slow and gave very inaccurate results in practice. This method was discovered by Mr. Hutchinson and communicated to Mr. Bolas in his office, but it gave very different results in their hands to those described by Dr. Weber.

Mr. BELL corroborated Mr. Heys' remarks.

Mr. TERRY said that looking at the paper as a whole there would have been a greater element of novelty in it if it had appeared before the recent papers of Henriques and of De Bruyn and van Leent. With regard to the method for the estimation of substitute, he must repeat a former observation, that although detailed methods might not before have been published, yet they had been worked out by those who required them. He had known, but had not used the method, ascribed to Bolas, but had preferred to work more on the lines laid down in the paper, and by which satisfactory results could be obtained. Some of the solvents employed by Dr. Weber were new to him in this application, and he hoped to be able to experiment with them on bodies of known composition, which as Dr. Weber had pointed out was the only reliable guide. He agreed with the observation that it was possible to attach too much importance to the physical tests unless such tests were supplemented by analysis; and he would also like to add that some practical experience with rubber on the part of the operator was very desirable also.

Dr. WEBER said with regard to the remark of Mr. Heys he would be glad to substitute the name of Mr. Hutchinson for that of Mr. Bolas. It was quite possible that his information with regard to his process for the analysis of india-rubber was not complete. Such information as he had was given in the paper, but he was able to dissolve a fraction of the india-rubber only. Mr. Bell confirmed Mr. Heys' statement as to the reliability of the method, but that confirmation would carry little weight, unless he could show that he tested the process by analysing samples of known composition. If they got an india-rubber article to analyse, they did not as a rule get at the same time a description of its component parts, and any method would give some result whether correct or not. He had not given a single analysis in this paper of an article the composition of which he did not exactly know. There was something more important than the mere analysis. The difficulty really began just when one required to interpret one's own results.

#### ON RESIST AND DISCHARGE STYLES WITH ANILINE BLACK.

BY CHARLES DREYER.

THERE are few colours that have rendered greater services to the calico printer and to the dyer than aniline black, the invention of which is due to John Lightfoot, of the Broad Oak Printworks at Acerrington, who patented his invention in the year 1863.

The depth of shade, the beauty of the colour, its great fastness to all reagents and to light, called immediately on its appearance the attention of chemists and colourists all over the world to its production.

It is not our intention to-night to give you a full history of the progress made in the application of this black for dyeing and printing; this has been done amongst others by the inventor himself in "The Chemical History and Progress of Aniline Black," published in 1871; by my esteemed friend Professor Noeltling in a work published in collaboration with Dr. Lehne entitled "Anilinschwarz und seine Anwendung in Färberei und Zeugdruck," published in 1892, a book we can highly recommend to all chemists and colourists who occupy themselves with the production of this colour, and of which it is to be regretted that no English translation has as yet appeared; and finally by Dr. A. Kilmeyer in a publication dated 1893, and entitled "Die Entwicklung des Anilinschwarz in der Druckerei und Färberei." The information contained in these publications is of such value that no calico printer and no dyer should be without them. It will be sufficient if we tell you that a high degree of perfection has been attained in the application of this colour in printing and in the dyeing of yarn, raw cotton, and piece goods. We believe it is no exaggeration to state that the weight of goods dyed and printed with this colour at present is equal if not superior to that made with any other colour.

Our object to-night is to call your attention to the progress made in the production of styles in printing with aniline black; at first it was used in the place of logwood blacks in most styles where such blacks were used; it was useful to print it with mordants which had to undergo dyeing with madder or its derivatives. Next the colourists aimed at producing effects by printing colours that would resist the black, namely, prevent the black from being formed at all points where such resist colours were printed, allowing the resist colours to appear in their own shades. It is believed that finer effects, clearer cut outlines of patterns are produced by the discharge method, consisting in printing or padding the cloth with the colour which after oxidation or steaming produces the black, but immediately after the printing or the padding of the colour for black a colour or colours are printed containing substances which prevent the formation of the black.

In connexion with aniline black, the expression of "discharge color" is not to be understood in the sense that the black is discharged after it has been formed, the nature of the colour prevents that. Take for example the case of indigo blue: such blue is discharged, and white is produced in the places where a color containing chromates of alkalis is printed and passed afterwards in a solution of sulphuric and oxalic acids.

In the case of aniline black, the discharge colour must be printed before the black has had time to oxidise, it should be considered as a resist-discharge, as we shall see later on in speaking of "Prudhomme's" method.

To understand the action of "reserves" and "discharges" on aniline black, it is necessary that a short sketch of the theory of the formation of the black be given.

Aniline black is formed by the elimination of hydrogen from aniline, this can be done by various oxidizing substances, such as chlorates, chromic acid, &c., in the presence of a trace of free acid, or in the case of the chlorates, in presence of a metallic salt, the chlorate of which is easily decomposed; a solution of pure chlorate of aniline may be boiled without any aniline black being formed, but immediately a drop of acid or of a copper salt is added to the solution the formation of black takes place at once. In the

same manner pure bichromate of aniline is fairly indecomposable into black, but if a drop of acid be added to a solution of bichromate of aniline the black is formed immediately; we may therefore conclude that black is only formed in the presence of a trace of free acid, and on this fact are based the various methods for resist printing with aniline black. We have, therefore, to look to alkaline substances or substances capable of neutralizing free acids, as capable to be employed as resists for aniline black, this is the opinion of most writers on the subject; we would add that besides these should be named also reducing substances or a mixture of the two; Witz recommends a mixture of 300 gr. acetate of soda and 300 grms. sodium hyposulphite per litre, or thickening as a good resist. To produce white on aniline black grounds, the following have been used:—

Caustic soda, carbonate of soda, silicate of soda, arsenite of soda, hyposulphite of sodium (100 grms. per litre), pyrogallie acid, recommended by Horace Koechlin; acetate of soda, chalk, zinc dust, albumen, aluminate of soda, citrate of soda, and sulphocyanides, recommended by Storek and Strobel (Wagners Jahresberichte, 1879), 50 gr. of sulphocyanide per litre are sufficient; by this process resists in all colors can be produced by simply adding either to an albumen color or to a tannic acid colour 50 to 60 grms. per litre of a sulphocyanide, and in the case of acid colours a suitable quantity of lead sulphocyanide.

#### *Discharge method of Prudhomme.*

We mentioned above the discharge method of Prudhomme, which for reasons given we preferred to call a "resist-discharge" method. This method has been used so successfully that we will give it in detail. The colour for padding used by him is made as follows:—

1,500 grms. chlorate of potash.

40 litres water.

4,000 grms. solution of ferrocyanide of potassium

28 per cent.

2,600 grms. aniline salt, and

X aniline oil.

The aniline salt (aniline chloride) should be as neutral as possible, and the quantity X of aniline oil to be added to the colour will depend on the composition of the aniline chloride.

Kertesz has published an improvement on Prudhomme's process; his colour is made as follows:—

{ 3,500 grms. chlorate of soda.

{ 20 litres water.

{ 5,500 grms. aniline oil.

{ 6,250 " hydrochloric acid at 19½ Baumé.

{ 10 litres water.

12 litres ferrocyanide of ammonium, bring the whole to 63 litres.

The ferrocyanide of ammonium for above is made as follows:—

A { 18 kilos. ferrocyanide of potash are dissolved in 32 litres water.

B { 9 kilos. ammonium sulphate are dissolved in 13 litres water.

Mix A and B in cooling, sulphate of potash crystallises out, and the clear solution is used.

The piece goods are padded with this solution and dried carefully. The temperature of the drying room should not go higher than 38 per cent., from this careful drying depends the success of the discharge operations.

The goods should be printed as soon as possible with the various discharge colours, of which we give a few:—

#### *Discharge White.*

3,000 grms. acetate of soda.

2,000 " soda ash.

4,000 " starch paste after cooling, add

250 c.cm. bisulphite of soda at 38° Baumé.

All pigment colours can be used as discharges by simply adding to them some soda ash, and aniline colours have also been used as discharges with suitable substances added to them.

After printing of the discharge colours the goods are steamed through the Mather and Platt steaming apparatus once or twice and passed through a hot bath of bichromate of potash (1—1,000), then washed, soaped, washed again, and dried.

A new departure in styles with aniline black has been made in the year 1892, and strange as it may seem it is again the Broad Oak Printworks of Accrington who have been the pioneers in this field of research. The patent taken in the names of Francis Frederick Grafton and William Browning is dated 18th June 1892, and states that:—

"The invention relates to an improved process or combination of processes for the production and fixation of colours, in conjunction with aniline black upon calicoes and other woven fabrics."

the claims are:—

"The simultaneous production and fixation of coloured designs in conjunction with aniline black grounds upon calico or other woven fabrics, by the combined process of combination of processes that follow":

"Firstly, prepare or mordant the cloth with an astringent solution and tartar emetic.

"Secondly, pad with a mixture of aniline oil and other materials thickened or otherwise, suitable for the production of aniline black by the ordinary known methods.

"Thirdly, print the design with colouring matters (such as are ordinarily fixed with astringent solutions) dissolved and thickened and mixed with acetate of soda or other well-known materials such as are used to prevent the formation or development of aniline black on the parts so printed.

"Fourthly, develop the aniline black (on the parts not printed) by steaming or ageing as usual which will at the same time cause the mordant or astringent matter to fix the colouring matters and resist or prevent the formation of the aniline black upon those parts which have been printed."

These are the claims set forth in that patent, they differ as you see from Prudhomme's method in so far that tannate of antimony is fixed on the cloth, previously to padding with the aniline black colour, such tannate of antimony acting as a mordant for basic aniline dyes and fixing them effectively after the steaming operation to which the goods are subjected afterwards.

We have seen goods produced by the above method which are excellent in design, in effectiveness and clearness of the finest lines in the pattern.

The next patents in order of date, which seem to be closely allied to the above, we find taken in America both on the same day, namely, the 14th February 1893, G. Donald of North Adams claims first, the padding of the cloth with an astringent or a metallic salt, if he pads with the one he adds the other to the aniline black colour with which he pads the cloth afterwards. He then prints the colour containing a substance or substances capable of resisting the fixing of the black (like Grafton) and a colouring matter combining with the tannin mordant previously fixed on the cloth, finally he steams to fix the colours and to develop the aniline black.

We leave you to judge where the improvement in Grafton's method can be seen in the above process.

F. P. Pearson of North Adams pads first in a colour capable of producing aniline black, then he prints the colour mixed with an astringent and a resist for the black, he steams or ages and passes finally through a solution of tartar emetic or tin salt to fix the basic aniline dyes.

We have not mentioned in its order of date the patent taken on the 12th January 1893 by the Thornliebank Company, Limited, Glasgow, and William Edward Kay, the two previous patents of Donald and Pearson having such obvious resemblance with that of Grafton's that we considered it better to give them in succession to the latter.

The claim of the Thornliebank Company and Kay are:—

1st. Preparation of the cloth with a mixture of aniline oil and other ingredients capable of developing aniline black, one of such ingredients being a ferrocyanide.

2nd. Printing of the design with a thickened paste containing (a) a solution of a suitable aniline or coal tar colour, and (b) acetate of soda, acetate of zinc, or other suitable reagent capable of preventing the development of aniline black.

3rd. Steaming or ageing the fabric in the manner usually followed for the development of aniline black.

The remarkable part in this invention is the observation made by the inventors that certain aniline dyes (we presume the basic dyes) are sufficiently fixed without the addition of any mordant when printed on the cloth prepared with an undeveloped aniline black mixture, one of the ingredients of which is a *ferrocyanide*; this observation should be followed out to its logical conclusion and experiments should be made to know if ferrocyanides do actually act as mordants for basic aniline dyes and fix them as effectually as tannic acid and emetic mordants.

Finally the inventors state that the order of the padding and the printing processes may be reversed.

On the 11th of April 1893, William Thomas Whitehead, of Magog, Canada, took out an English patent for improvements in resists or discharges for use in printing or dyeing cotton, &c. with aniline black; the invention consists in the use of oxides of zinc, &c. as a resist or resist discharge for aniline black, alone for producing whites, or mixed with pigment colours, aniline dyes, or dyewood extracts, for producing coloured patterns on aniline black grounds.

This inventor also made the curious observation that pigment colours and some aniline dyes, principally the basic dyes, are fixed by the ingredients contained in the aniline black colour in conjunction with the oxide of zinc, &c. without the addition of albumen to the pigment colours or of any other mordant in the case of the aniline dyes; this is, in our opinion, a valuable part of this invention and leads us to ask the question: What is the chemical or physical action that takes place to enable the oxide of zinc, and the other substances contained in the aniline black colour to fix pigment colours?

The fixing of the basic aniline dyes is already explained, partly at all events by the observations of Kay, and we shall take an early opportunity to try and ascertain the nature of the fixing action of the above substances on pigment colours.

We have been informed that Whitehead's process which is in use in many printworks in America has given satisfactory results.

Mr. John Riley of Thornliebank fearing that he could not be present this evening wrote to us as follows:—

"In May 1880 I introduced oxide of zinc as a resist for aniline blacks, and it has been in use at Thornliebank regularly since that date, for whites and pigment colours resists. The introduction of this insoluble resist enabled us to print the designs and steam one hour to fix the colours before padding the aniline mixture; it was used by us as a resist and not as a fixing agent."

It is possible that further patents exist on these interesting styles, but we have not had the leisure to search for them all.

We have endeavoured to lay before you, as fairly as possible, the methods lately discovered for producing valuable styles with aniline black, and so call specially the attention of those interested to the possibilities of further discovery and improvements in them, and I see present amongst you the leading chemists and colourists of the district, so that I can feel certain that the idea will be properly taken up and that the seed which I have sown will not fall into barren ground. This country has certainly made immense progress in the art of calico printing these last 20 years, and I hope it will continue to occupy the front rank in this difficult industry. I think papers bearing on some subject of the industry should be brought oftener before our section, and I hope we shall see more of them by members who are specialists in this branch brought before us next session.

## DISCUSSION.

Dr. Winkler said one of the mordants Dr. Dreyfus had mentioned was ferrocyanide, the mordanting properties of which he (Dr. Dreyfus) seemed somewhat doubtful about. He could, however, thoroughly bear out the property of ferrocyanide, or rather of hydroferrocyanic acid, to form lakes with the basic dyes, so that if we have either cotton prepared with ferrocyanide and treated then in a solution of a basic dye; or if the cotton is first impregnated with a solution of the basic dye and then treated with ferrocyanide in both cases the colour becomes fixed upon the cotton, the fastness of these lakes to light and washing is however very small, and cannot be increased by the forming of a compound lake as it could by treatment of a tannin lake with tartar emetic.

## Dorsetshire Section.

Chairman: A. Smithells.

Vice-Chairman: T. Fairley.

### Committee:

J. E. Bedford.	C. Rawson.
F. Branson.	F. W. Richardson.
J. B. Cohen.	Jas. Sharp.
J. J. Hummel.	G. W. Slatter.
J. Leckowitsch.	G. Ward.
W. McD. Mackay.	T. B. Wilkinson.

### Hon. Local Secretary:

H. R. Procter, Yorkshire College, Leeds.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman:* C. F. Tetley. *Vice-Chairman:* J. J. Hummel. *Committee:* T. Fairley, W. Leach, A. G. Perkin, and Thorp Whitaker.

Meeting held at the Queen's Hotel, Leeds, on Monday, May 7th, 1894.

PROFESSOR SMITHELLS IN THE CHAIR.

## ON THE QUALITATIVE DETERMINATION OF TANNING MATERIALS.

BY H. R. PROCTER, F.L.C., F.C.S., LECTURER ON LEATHER INDUSTRIES AT THE YORKSHIRE COLLEGE, LEEDS.

THE following paper is an amplification of one which was read at the Chicago "World's Congress of Chemists" last year, and my excuse for bringing it before you to night is that it has not as yet appeared in any English paper, and that I would rather that it did so with some emendations and additions which further experience has suggested.

It can hardly be said that any systematic attempt has been made to formulate a scheme for distinguishing the various tanning materials by their qualitative reactions, except perhaps a very slight table published by the writer, although, in view of the constantly increasing number of new tanning materials, and especially of new extracts which are offered to tanners, the matter has become one of considerable practical importance. The commercial value of an extract is dependent, not only on the percentage of

tanning matter as determined by analysis, but on the nature of the tannin present, which influences the character of the leather produced.

It is, of course obvious, that, failing a clear knowledge of the tannins themselves any really scientific scheme of separation is for the present impossible; since, although we have good reason to believe that the tannins are a class, we are quite ignorant of their number, which may easily be a comparatively small one, since many members of the group which at present receive individual names are probably mere mixtures. All that can be done at present is to separate the tanning materials into groups or individuals by reactions which have been empirically determined; of which in many cases we do not know the chemical significance, and which are often due to other constituents of the material than the tannins themselves. The question is still further complicated by the fact that woods, barks, and fruit of the same tree often yield tannins of distinctly different character. Thus the bark of *Acacia arabica* [Babul] gives the general reactions of the Australian acacias, and evidently contains as its main constituent a tannin of the catechol group, while the pods of the same tree have a tannin which differs from any other which I have examined, but which is apparently a pyrogallol derivative. The differences between the tannins of oak bark, galls, and wood are equally striking. And while cutch from the wood of *Acacia catechu* gives the phloroglucol reaction intensely, the bark of the same tree hardly contains a trace.

Perhaps before proceeding to discuss means of identification, I may be permitted briefly to sketch what is known of the chemistry of the tannins, since, though it is as yet impossible to determine them on a really scientific basis, it is well to keep this steadily in view.

The tannins form a widely distributed class of vegetable products of varied constitution, but which is characterised by the power of precipitating gelatin and allied bodies from their solutions, of tanning animal skin, and of giving blackish colorations with ferric salts. So far as is known, all are derivatives either of the dihydric phenol, catechol, or of the trihydric, pyrogallol, while many of them contain in addition phloroglucol, which is isomeric with pyrocatechol, and is generally regarded as being also a trihydric phenol. The tannins frequently exist in some sort of connexion with glucose, but not as true glucosides, since by purification the glucose may be removed without apparent change in their properties.

The only tannin with the constitution of which we are even fairly acquainted is gallotannic acid, the ordinary tannin of the shops, prepared from galls, and, synthetically by Schiff's method of treating gallic acid with phosphorus oxytrichloride. Gallic acid is derived from pyrogallol by the introduction of a carboxyl group, as is salicylic acid from ordinary phenol; and gallotannic acid appears to be an anhydride of gallic acid, bearing a relation to it somewhat similar to that of the lactones to the oxy-fatty acids. From either gallic acid or its derived tannins, pyrogallol is obtained by the simple action of heat, which removes the CO<sub>2</sub> of the carboxyl group. By hydrolysis of gallotannic acid, gallic acid is restored.

There is another tannin, known as ellagettannic acid, which is evidently closely allied to gallotannic acid, and almost invariably exists in conjunction with it in tanning materials, and which, when hydrolysed, yields a pale crystalline solid, scarcely soluble even in boiling water, and which is apparently analogous to gallotannic acid, but less two atoms of hydrogen. This is ellagic acid, which is of considerable technical importance as constituting the pale deposit of "bloom" which occurs in leather tanned with these materials. The constitution of the tannin is unknown, but a rather striking colour-reaction with nitrous acid appears to be characteristic of all tanning materials which contain it.

Of the actual constitution of the large class of tannins which yield catechol on heating we know very little. Instead of hydrolysing when heated with water or dilute acids, they appear mostly to yield series of red anhydrides, the lower members of which are dark coloured and

difficultly soluble tannins, and the higher, still of an acid nature, and quite insoluble in cold water, but soluble in alkaline solutions, are "phlobaphenes," or "reds," possibly allied to the resins. It is only after pretty severe treatment of these with caustic alkalis, that they split up into protocatechuic acid, which is related to catechol as gallic acid is to pyrogallol, together with phloroglucol and other bodies.

It would obviously be most scientific and satisfactory to classify the tannins by these decomposition products, but unfortunately the latter are so unstable, and so difficult to separate, that this is impracticable, and we have to fall back on reactions which do not demand actual isolation of the constituents. One of the oldest of these is the colour reaction with ferric salts, with which catechol and protocatechuic acid give dark green colorations, while pyrogallol and gallic acid give blue-blacks, and these peculiarities usually extend also to their derivatives. As a reagent for this purpose I employ—

**Ferric Alum, Ammonia Ferric Sulphate.**—A one per cent. solution of this salt has been chosen as easily obtainable, neutral, and in a state of approximate purity. Ferric chloride, which is generally used, is almost invariably strongly acid, and of a very persistent yellow. Acid ferric chloride in excess will give a green-black reaction with gallotannic acid itself, and its results as a test are often misleading. Ferric acetate, which has also been largely used, gives heavy precipitates with most materials, and is very strongly coloured, so that it was found less convenient than the iron alum. As the colorations are generally very powerful, they are best seen by diluting the tanning infusion freely, and adding the iron solution very cautiously. In many cases the coloration first produced, and which is the characteristic one, rapidly fades to a dull olive or brown in presence of excess of iron, probably by oxidation and destruction of the tannin.

It may be pretty safely assumed that any tannin which gives a distinctly greenish black with iron is a catechol derivative, but there are a large number of materials, especially among the acacias or mimosas, which give purplish blacks, but are pretty certainly catechol tannins; and on the other hand the oak barks which Trimble has proved to be catechol tannins, and most of which give green blacks with iron, also yield bloom or ellagic acid, and are therefore also allied to gallic acid. Another reagent is therefore employed in the preliminary classification, viz., Br. water.

**Bromine Water Reaction.**—It is best to add the bromine water drop by drop to 2–3 cc. of the infusion in a test tube, until the solution smells strongly. In some cases the precipitate is slight, or forms slowly, and occasionally it is crystalline and on this account less conspicuous, but it is usually a distinct yellow or brown flocculent one. In general terms it may be said to be a reagent for the catechol tannins; precipitating all which give green blacks with iron, and many which give blue or violet-blacks, which are reasonably suspected of containing catechol. It does not precipitate any recognised pyrogallol tannin, but several which yield ellagic acid (bloom) such as oak barks.

Tannins may therefore be divided into three classes, as in table I, viz.:—(1) those which give a precipitate with Br. water, and green blacks with iron alum, and which are pretty certainly catechol tannins; (2) those which give a precipitate with Br. water, but bluish or violet blacks with iron, and which for the present must be regarded as mixed or uncertain; and (3) those which give no precipitate with Br. and blue-blacks with iron, and which, so far as we know are all derivatives of pyrogallol.

By far the largest number of tannins fall into class 1, but these may be pretty satisfactorily subdivided by a reaction with—

**Cupric Sulphate and Ammonia.**—When solution of cupric sulphate is added to a tanning material infusion, it sometimes gives a precipitate, and sometimes not. This is a useful indication in some cases, but must not be regarded as of first rate importance, as the presence of any salt of a weak organic acid would in all cases cause a precipitate, by neu-

tralisising the sulphuric acid of the sulphate. Cupric acetate produces a precipitate with all tannins so far as I have observed, and it is interesting to note that in this case, as in many others of a like character, the tannin combines with, and precipitates the salt as a whole. On the addition of ammonium carbonate, effervescence takes place, and the precipitate darkens, and becomes a true tannate.

When ammonia is added to the mixture of a tannin and cupric sulphate, a precipitate is invariably formed in the first instance, consisting of a tannate of copper with variable quantities of blue cupric hydroxide. With excess of ammonia, the whole of this precipitate is in many cases dissolved, while in others, an insoluble tannate remains. The latter is the case with all tannins derived from gallo-tannic acid, and with many containing protocatechuic acid, and forms a useful means of classification, though as yet the difference of structure to which it corresponds is unknown. The fact that hemlock and other pine barks, as well as cutch and gambier, yield cupric tannates soluble in ammonia, is an instructive commentary on processes which have been proposed for quantitative estimation by precipitations by ammonio-cupric solutions.

Where the precipitate redissolves, it generally does so with the production of either a greenish brown, or a purplish brown coloration, which in presence of a small amount of the blue ammonio-cupric sulphate, appears either as a green or a reddish violet. It need hardly be pointed out that to see this coloration well, the copper should be in the least possible excess. Hence it is desirable to use a very weak copper solution, say at most one per cent.

We thus obtain two sub-classes: 1  $\alpha$  (Table II.) in which copper produces a precipitate soluble in ammonia and 1  $\beta$  (Table III.) in which an insoluble precipitate is formed.

No attempt has been made to arrange systematically the results of the further reactions which are suggested to determine individual members, since in the main they correspond to no broad chemical demarcation, and in others they shade off by imperceptible degrees, so that it is only by taking all characteristics into account that any safe conclusion can be drawn. This is specially the case with the vanillin reaction for phloroglucol, which is given strongly by cutch and gambier, markedly by several other materials, and so faintly by many others that no sharp line can be drawn. The following reactions are those which I have employed for further distinction:—

**Nitrous Acid Reaction.**—This reaction, which is believed to be a new one, is obtained by adding to a few cc. of the very dilute infusion in a porcelain basin a distinct excess of freshly prepared solution or a few crystals of sodium or potassium nitrite, and then 3–5 drops of decinormal sulphuric or hydrochloric acid. In typical cases the solution instantly turns pink or crimson, and slowly changes through purple to a deep indigo-blue, but in others, as sumach, where the reaction is feeble, and masked by other changes, the final colour is green or even brownish. In a large number of cases, nitrous acid produces a yellow or brown coloration or precipitate, but "reaction" in the tables invariably means a series of colour-changes as above-described. Nothing can as yet be said on the nature of the chemical changes produced. The reaction is given by all tanning materials which yield ellagic acid or "bloom," but not by ellagic acid itself, nor by pure gallo-tannic acid. It is therefore probably a reaction of ellagitannic acid, and is valuable for subdividing the mixed and pyrogallol tannins. It may also be obtained faintly from some of the oaks in Class 1  $\beta$ .

**Stannous Chloride and Hydrochloric Acid.**—This reagent consists in a strong solution of stannous chloride in concentrated hydrochloric acid. If about 10 cc. of this are added to 1 cc. of the tanning material infusion, in a porcelain basin, and allowed to stand for 10 minutes, coniferous tans, mimosas, and some others give a very marked pink coloration. This is specially distinct in the case of larch bark. If a small piece of larch-tanned leather be steeped in the reagent, the coloration appears very strongly.

**Deal Shaving and Hydrochloric Acid.**—A shaving or slip of any pine wood is moistened with the infusion, and then, either before or after drying, is again moistened with concentrated hydrochloric acid. In the case of cutch and gambier, and a few other materials, and of solution of phloroglucol itself, the spot becomes at once a bright red or violet, but in many cases the reaction is faint, and only appears after some hours. It probably always indicates the presence of phloroglucol. The statement that catechol gives a similar reaction appears to be an error.

**Sodium Sulphide.**—This was mentioned in my previous manuscript on the subject, but the printer unfortunately substituted sodium sulphide, which does not answer in the laboratory!

A few drops of the solution are placed in contact with a crystal of sulphite on a tile or in a basin. With valonia, a bright purplish pink is rapidly developed, apparently by oxidation. Many other tanning materials produce red or pink colorations, but in no case so marked a reaction as valonia.

**Concentrated Sulphuric Acid.**—A test tube is rinsed out with the infusion and drained so that only about a drop remains, and about 1 cc. of concentrated acid is cautiously poured into the sloping tube, so as to form a layer underneath the tanning solution. The ring of colour at the junction of the two liquids is noted, and then they are mixed by shaking and diluted with water. About half the materials give a deep purplish crimson, called simply "crimson" in the tables, and in many cases this is decidedly pink on dilution, while in others it is obscured by brown products formed by the heat of mixture. A large number of other materials give browns or yellows only, which, when intense, may appear red, but dilute to yellows or yellow-browns.

**Lime Water** is a most useful reagent, being very varied in the colour of the precipitates it produces, and the changes they undergo by oxidation. The reaction is best seen in a shallow porcelain basin, and time must be allowed for the changes to take place. It may be safely added in considerable excess.

**The infusions of Tanning Materials employed** are understood to be of about the strength used by the writer in determinations by hide-powder, viz., about 0.6 gm. of dry soluble matter in 100 cc., but moderate divergencies from this do not influence results. Of course, where reactions are feeble, with very dilute solutions they may be imperceptible, and on the other hand, strong solutions will sometimes give precipitates where only colorations are noted with weak ones. As some of these reactions are dependent, more or less, on the concentration of the infusion employed it is desirable to experiment in the first instance with known materials in order to acquire a little experience of exact conditions.

In some cases these reactions will serve to determine the constituents of mixtures, but in others this will continue impossible till further and more distinctive reactions are discovered.

They can of course be applied to the recognition of tannages, when excess is present in leather, which can be dissolved out with water; but the effect of dilute alkalis and other solvents on the reactions is worth further experiment.

It was thought that some information as to the meaning of the reactions employed might be obtained by examining the behaviour of the simpler derivatives under the same circumstances, and the results are given in Table X. It will be at once obvious that the blue-black reaction with iron is characteristic of the pyrogallol group, and the green-black equally so of the catechol derivatives, while phloroglucol, contrary to the statements of the text-books, gives no marked reaction with iron, but is the only member of the group characterised by the very delicate reaction with the vanillin present in deal. On the remaining reactions little light is thrown.

TABLE I.  
PRELIMINARY CLASSIFICATION OF TANNING MATERIALS.

Fe. Water produces a Precipitate. Iron-Alum gives Greenish Blacks. (Catechol Tannins.)		Br. Water produces a Precipitate. Iron-Alum gives Blue or Purplish Blacks. (Mixed and Doubtful.)		Br. Water produces no Precipitate. Iron-Alum gives Blue Blacks. (Pyrogallol Tannins.)	
Copper Sulphate followed by Ammonia in Excess.		Sodium Nitrite and 5 drops $\frac{N}{10}$ HCl.		Sodium Nitrite and 5 drops $\frac{N}{10}$ HCl.	
Precipitate redissolves.	Precipitate does not redissolve.	No reaction, or, at most, darkening.	Some Colour-Change through Red towards Blue or Green.	Colour-Change through Red to Blue.	No reaction.

## NOTE ON THE ESTIMATION OF TANNING MATTER.

BY H. R. PROCTER, F.I.C.

THERE is much for which the leather trade should thank the Imperial Research Station for Leather Industries at Vienna, and not the least of these benefits is the invention of the indirect gravimetric method of tannin estimation published by Simand and Weiss (Dingl. Polyt. J. 260, 564; this Journal, 6, 94) in 1887, and now used in various modifications by leather chemists practically to the exclusion of every other, the Löwenthal method only retaining a certain place for special purposes. In its original form the process consisted in evaporating a given quantity (50 or 100 cc.) of the tannin infusion to determine total solids, while to another portion, carefully purified powdered hide is added in five or six successive small quantities at intervals of six or eight hours, so as to avoid the hardening effect which strong tannin solutions exert on hide if added all at once; and the filtrate from this is again evaporated to determine the solids remaining, which represent the "non-tannins," the difference between the two determinations giving the actual weight of the tanning substances absorbed. The principal drawback is the rather considerable time required for complete absorption (24–36 hours) and the consequent liability to putrefactive action in hot weather. This is reduced by the device used by Dr. Hellon, who sets the absorption flasks in a vessel of running water.

Almost immediately after the publication of the method, the present writer (this Journal, *loc. cit.*) suggested the use of a filter-tube charged with the hide-powder as a means of detanning. This was at once adopted by the Vienna Research Station with some improvement in the form of the filter, and is still used there with quite satisfactory results, reducing the required time to 2 or 3 hours.

A further modification was recently published in the "Leather Manufacturer" by Dr. Fiebing, of Milwaukee, Wis., with which I was much struck when I saw it in operation in his laboratory, and since that time have found it so satisfactory at the Yorkshire College Leather Industries Laboratory that we there use it for almost all tannin determinations. The principle of the new method is identical with that of Simand's original process, but instead of merely digesting with occasional shaking, the liquid is violently agitated for 10 minutes each time with three successive quantities of hide-powder, which has previously been thoroughly washed in at least two changes of water, and well squeezed. The shaking is best done with a "milk-shaker," a little machine constructed for the preparation of American drinks, and consisting of a vertical rod carrying clamps for two glasses with covers, which receive a rapid reciprocating movement (not less than 320 to 420 rotations of the crank per min.) from a crank driven by a multiplying wheel. In place of glasses I frequently use ordinary bottles of suitable size, with india rubber corks; and, as in my laboratory we have the convenience of an electric motor, I usually run rather over the time named for extra safety, although with 6 grms. of hide-powder in all to 100 cc. of infusion not containing more than 0.6 gram. of total solids, 30 minutes is sufficient to remove all tannin.

It is obvious that some correction must be applied to the results for the water introduced in the damp hide-powder. This is determined by pressing the latter in folds of cloth in a copying press, and re-weighing to ascertain gain in weight, each gram. of which is reckoned as an addition of 1 cc. to the volume of the solution employed. Even if this is not strictly accurate, any small error has only a vanishing influence on the result.

In addition to the saving of time, the process has the advantage that it gets rid of the rather dubious correction for solubility of the hide-powder sometimes used in Simand's original method, and hence will give good results with powders which are useless either for this or the filter method. Thus, an experimental powder was prepared

from the sawdust of buffalo-hide pickers (a manufacturing waste worth about 5d. per lb.) by washing first with dilute sulphurous acid, then with abundance of tap-water, and finally with distilled. This was dried by spreading on paper in a warm room, and ground through the Burroughs and Wellcome's drug mill, which we use for samples of tanning materials. It formed a somewhat greyish-white

powder, much heavier and less bulky than the Vienna powder, and proved quite useless in the filter from its compactness, and the difficulty of wetting it, probably due to traces of fatty acids. Used in the "shaker," the results agreed most satisfactorily with the Vienna powder, and we now rarely use anything else, as the saving in cost is very considerable. Vienna powder costing here about 10s. 6d. per lb.

The following experiments made by Mr. E. Dewez, one of my students, to determine whether the speed of the motor had any influence on the amount of matter dissolved from the powder, show also very clearly to how small an extent it can influence the results of an analysis. 6 grms. of the powder were shaken for half an hour at the highest speed of the motor with 100 cc. of water, when 50 cc. of the washings filtered through paper and evaporated left 18 mgrs. of solids, of which 9 mgrs. was inorganic. It was then washed a second time for 10 minutes, when 50 cc. gave only 4 mgrs. residue. A second experiment at the slowest speed gave for the first washing 14 and for the second 2 mgrs. residue. The washed powder of the first experiment, which must have given up much less than 4 mgrs. to a third washing, was now used to detannise 100 cc. of an extract liquor as before described, and gave a result of 7.91 per cent. of non-tannins in the sample of extract, while a parallel determination with Vienna powder and the siphon filter gave 7.81 per cent.

In my opinion the only satisfactory way of dealing with the soluble matter in hide-powder is to eliminate it to such an extent that its influence may safely be disregarded, any attempt to determine its quantity and apply a correction being rendered uncertain by the fact that it consists to a large extent of partially altered hide, which is precipitated by tannin, and consequently is less soluble in tanning infusions than in pure water. With a good powder in the hide-powder filter it is practically eliminated by rejecting the first portion (of say 30 cc.) which comes over, but such a powder should be carefully tested before use to ascertain that after running 50 cc. the residue left by the next 50 is negligible. To give an idea of the limit allowable, I may

point out that on a 20 per cent. material each milligramme will be approximately equal to 0.1 per cent.

In an important paper, *Ueber Eine wichtige Fehlerquelle der gewichtsanalytischen Methode der Gerbstoffbestimmung* (Ding. Polyt. Jour. 280, Heft 6 and 7), Dr. R. Koch points out the very varying quality of commercial hide-powders, and mentions one, of which 7 grms. gave no less than 0.258 gm. of soluble matter! He further draws attention to the fact that in his hands, powders which had undergone some degree of incipient putrefaction, and which consequently gave much soluble matter, gave different, and indeed higher results than normal powders to the extent of sometimes 2 per cent., even after thorough washing. This variable absorptive power has also been confirmed by Dr. Fiebig, and especially by Mr. Westenfelder, of Cincinnati (both, I am glad to say, members of our Society), the latter of whom furnished me with the results of a long series of analyses bearing it out. Dr. Koch states as necessary characteristics of a good hide-powder for the filter method (which was used by all three chemists named), that the powder must be white, rather inclining to yellow than grey, fine and woolly, not powdery, and especially without any unpleasant putrefactive smell. The Vienna powder possesses these characteristics in a high degree, as also does one supplied me by Messrs. Reynolds and Branson, while my buffalo powder presented a perfect example of all the objectionable features condemned, and even after purification does not recommend itself by appearance; and yet, as I have shown, gives results by the "shake" method which agree perfectly with those of standard powders. This bears out the assertion that the "shake" method is far less dependent on the character of the powder than the filter method; but as it was quite impossible to use the buffalo powder in the filter, I am unable to test it directly. It is possible that the use of sulphurous acid in the purification of my powder may have removed the objectionable features complained of, but in the meantime I am inclined to attribute the error rather to the mechanical than the chemical state of the putrefied powders. I am not at all sure that with the American chemists it was the worse powders that gave the higher results, as with Dr. Koch. It is in any case important to employ the best possible powders, at least on check analyses, and to make quite sure, by means of comparative tests, before using one of more doubtful appearance, that it has no adverse influence on the accuracy of results.

#### DISCUSSION.

Mr. A. H. ALLEN said that he had been much interested in Mr. Procter's paper, and looked forward to seeing it in print. The subject of the recognition of tannin matters presented great initial difficulties. He thought that the classification of various kinds of tannin together simply because they precipitated gelatin resulted in the grouping of substances which did not necessarily belong to the same class, any more than copper, chromium, and nickel could be analytically classed together simply because their salts formed green solutions. He was interested to know that the nitrous acid test had yielded good results, though it was disappointing to find that Mr. Procter had not yet ascertained all the conditions of success. He thought that Mr. Procter had done wisely in substituting iron alum for ferric chloride, which certainly gave very erratic results, the ordinary laboratory reagent being of very indefinite nature. He was interested in Mr. Procter's results with copper acetate, as he had recently been employing it for an entirely different purpose. With the exception, perhaps, of lead acetate, it had a more general precipitating power than any other metallic salt. Some 20 years since he had described a reaction for gallotannic acid, or rather the tannin of tea, which was very delicate, and consisted in the red coloration produced with a solution of potassium ferrieyanide to which excess of ammonia had been added. He did not at that time extend his examination to many other kinds of tannin, and should be glad to learn if Mr. Procter had made any experiments in that direction. He should also like to know if Mr. Procter had succeeded in detecting phloroglucin in the product obtained by fusing

catechol and allied substances with caustic potash. He had tried many experiments in this direction, but had never succeeded in obtaining such a result as the books would lead one to expect. This was doubtless owing to his expecting to obtain a violet coloration with ferric chloride, which Mr. Procter has shown was not yielded by pure pyrogallol. As to the coloration produced by lime-water, experiments he made many years ago led to very erratic results when the test was applied in the presence of air. He had found, however, that interesting and more reliable results were obtained by operating in the absence of air. This he did by introducing the tannin solution into a nitrometer-tube filled with mercury. He then added through the tap lime-water or barite water, and observed the change. Then on gradually admitting air the changes due to gradual oxidation were conveniently observed. This method of manipulation might be advantageously employed in other cases where it was desirable to operate in the absence of air, or to admit air in regulated amount. Mr. Allen congratulated Mr. Procter on having found a simpler method of estimating tannins than that of Löwenthal, into which the personal equation entered far too largely. The examination of tannin materials was always a difficult problem, and different analysts did not always obtain concordant results.

Mr. RICHARDSON was glad that the use of hide-powder had proved satisfactory. What was understood by the term "tanning substance"? Did it include all substances that were absorbed by hide-powder? Surely other substances than tannins were so absorbed. He was surprised that nothing had been said of the use of basic acetate of lead. What was the action of mordants on tannins? He was under the impression that the action of tannins upon hide-powder was like that which they exercised in the dyeing process. Had Mr. Procter observed whether the action was different in the case of an iron and of a tin mordant?

Mr. BROADBENT was anxious to know how the hide-powder mentioned was prepared; could it be made from ordinary leather? What was the strength of the lime-water used, and had it been standardised?

The CHAIRMAN said he felt sure he might convey to Mr. Procter the thanks of the Section for his papers. The subject of the tannins was very complex and forbidding, but it was yielding, and would, no doubt, yield entirely to patient inquiry by the skilled specialist.

Mr. PROCTER, in replying, said that the number of the tannins was not so large as was generally supposed. Trimble had indeed been led, by his recent investigations, to think that there were only two. He had not studied the action of ammoniacal potassium ferrieyanide upon many tannins. Copper acetate probably precipitated all tannins perfectly. The nature of the precipitate was worth examining, the copper salt as a whole apparently combining with the tannin. The same was true of lead nitrate, which precipitated tannins without any liberation of free nitric acid.

Both neutral and basic lead acetates were general precipitants of tannins, and so hardly came within the scope of his inquiry, which concerned itself with qualitative recognition only.

He had done little work on the products of fusion of tannins with caustic potash; their instability under such severe treatment, and the great difficulty of separating them, were not encouraging. Fortunately the test for phloroglucin with deal shaving was so satisfactory that resort to fusion seemed unnecessary. The similar reaction reported of protocatechuic acid in the text books was probably due to impurity; a specimen he had from Kala Nam gave no trace of it, and, on the other hand, pure phloroglucin appeared to give no reaction with ferric salts, as would be seen by reference to Table VIII.

The use of the nitrometer for oxidisable solutions was an excellent device, of which he should certainly avail himself.

Hide-powder certainly did not absorb tannin only, but also acids, and many metallic salts, especially of the type of alum and aluminium sulphate, as well as other substances; as regarded mineral impurities, the nature of the ash of the extract gave some clue as to what would be absorbed by the powder. He was glad that the results of the hide powder and of the dyeing tests were similar; there was no *a priori* reason for expecting it.

The "buffalo-hide powder" was probably actually made from buffalo hide—not of the American but the Oriental buffalo; he had used it because it was the cheapest and most convenient material; it was otherwise not specially suitable for his purpose. The lime-water he used was a saturated solution, of strength about half decinormal.

### A RAPID METHOD OF DETERMINING THE SHADE OF ALIZARINE PASTES.

BY A. C. PERKIN, F.R.S.E., F.I.C.

THE following simple test, though little known to the outside world, is frequently used in most alizarine factories, and also to some extent in the Turkey red dyeworks in this country. As it provides a very accurate means of judging and comparing the shades of the various pastes rapidly, it should be useful to all users of this dyestuff, so that I have therefore thought it worthy of a communication to this society. It is well known that solutions of the alkaline hydrates readily dissolve alizarine, anthrapurpurine, and flavopurpurine, giving respectively blue-violet, crimson, and orange-red coloured liquids, containing the corresponding salts. This method of distinguishing between one or other of these substances has however this defect, that these solutions, necessarily dilute, rapidly alter and fade on standing, owing to oxidation. By employing the alkaline carbonates, preferably potassium carbonate, in the place of the hydrates, this difficulty is avoided, and coloured solutions of tolerable permanency obtained. The determination is carried out as follows:—Five grms. of the 20 per cent. paste is made up to one litre with distilled water, 5 cc. of this mixture treated in a flask of about 550 cc. capacity with 5 cc. of a 2 per cent. solution of potassium carbonate and then made up to half a litre with distilled water.

The coloured solution thus obtained can then be compared as desired with similarly prepared solutions of other pastes.

It is obvious that in the comparison of one paste with another by this means, flasks of similar diameter must be used, and further it is best that the solutions should be examined before a ground glass window, in order to avoid the shadows cast by outside objects.

With a little practice it is easy to detect very small differences in shade between two pastes, for instance an addition of 3 to 5 per cent. of anthrapurpurine to alizarine is discernible.

The composition of a paste may be also to some extent determined, for whereas the coloured solutions so obtained containing mixtures of alizarine and anthrapurpurine are clear and bright, on the other hand mixtures of alizarine and flavopurpurine are considerably duller, due to the yellow tint present in the alkaline solution of this latter.

With mixtures containing alizarine and both anthra and flavopurpurines, the analysis is naturally far more complex, many trials having often to be performed, and in cases of this kind the accuracy of the result should be further confirmed by a dyeing trial, using the usual mordanted calico. It is obvious, however, that by this method of testing the number of dyeing trials otherwise necessary is considerably reduced. Among other classes of alizarine colours with which this method can be used are the alizarine cyanines, and alizarine Bordeaux pastes, several shades of each being now in the market.

It is probable also that it would be of service with several mordant dyestuffs, which yield coloured liquids with carbonate of potash solution, and even possible that it could be used with advantage for determining by comparison the amounts of developed colouring matter in samples of log-wood and Brazilwood.

### DISCUSSION.

Mr. RICHARDSON asked why a tintometer had not been used with glasses to cut off the different shades.

Mr. SEATON remarked that the solutions could not, unfortunately, be kept permanently as standards, as they tended to fade.

Professor HUMMEL, in reply, said that the process as described by Mr. Perkin had proved in practice to be both rapid and accurate, and there would be no real advantage in making it more elaborate.

Mr. PERKIN, who was unable to be present at the meeting, desires to state, in reply to Mr. Richardson, that some advantage might be gained by the use of the tintometer, but it is doubtful whether the colour of the solutions was permanent enough for examination by this means. As regards the standard solutions, these are not kept in an alkaline condition, but, as stated in the paper, the requisite quantity of the standard solution is treated with potassium carbonate when required for comparison. The test as it stands is, to his knowledge, in frequent use, and is found to be of much service for the purpose.

### NOTE ON AN IMPROVEMENT IN DYEING LEATHER WITH BASIC COLOURS.

BY J. J. HUMMEL AND H. R. PROCTER.

IN applying basic coal-tar colours to cotton, it is well known that the latter requires to be mordanted with tannic acid. In the case of leather tanned with sumach and other similar tanning matters, such preparation is of course unnecessary, not only because the leather already contains tannic acid, but because the substance of the leather itself as a protein compound has a natural attraction for the colouring matter. Nevertheless, very poor results are frequently obtained in dyeing leather, *e.g.*, skivers, with the basic colours, the colours being pale or irregular. An examination of the dye-liquors in these and other cases revealed the fact that the colouring matter was very largely precipitated, due no doubt to tannic acid dissolving off the leather.

Two methods of getting rid of the defect naturally occur to one, *viz.*, to remove the excess of tannic acid present by previously steeping the leather in tepid water, or to render the excess inert by fixing it upon the leather in an insoluble form.

Both methods were tried with the result that the second proved to be the most reliable and effective. To this end it is merely necessary to work the leather in a tepid bath (45° C.) containing the requisite quantity of tartar emetic for  $\frac{1}{4}$ — $\frac{1}{2}$  hour, then to wash, before proceeding to the dyeing operation.

By adopting this simple precaution, the dye-liquors are maintained in a perfectly clear condition, and since they are invariably unexhausted, they can be used for dyeing further quantities of leather; moreover, the dyed colours are perfectly level, and many shades darker than without this preliminary treatment. The leather itself is in no wise injured, and since the antimony is in a perfectly insoluble form as a tannate, there can be no fear of injurious consequences arising in the ordinary use of such leather.

We are not aware that the method is adopted in practice, but after repeated trial on the small scale, we have every confidence in recommending it to the trade.

We may add in conclusion that our belief is that a judicious application of tartar emetic in limited quantity along with basic colours in the process of staining leather by brushing on, would in many cases be advantageous.

#### DISCUSSION.

Mr WILKINSON asked whether antimony fluoride or oxalate could not be used instead of tartar emetic.

Professor HUMMEL said they would no doubt do equally well.

#### SESSION 1893-4.

*Meeting held in the Philosophical Society's Rooms, 207 Bath Street, Glasgow, on Tuesday, March 7, 1894.*

THE HON. CLARK, F.R.S.E., in the Chair.

### ON THE SUITABILITY OF WATERS FOR DIETETIC PURPOSES AS SHOWN BY CHEMICAL ANALYSIS.

BY R. R. FAULKNER AND R. L. THOMSON.

The question of the suitability of waters for dietetic purposes is determined by the results of their analysis, is one on which every chemist is called upon to give his decision, and the interpretation of these results, and even the very methods in use, have been the subject of difference of opinion. This discussion has been once more reopened in the "Analyst" by Mr. F. W. Stoddart whose aim has principally been to plead for the inclusion of nitrates as one of the elements of proof of the presence of sewage in a water. We have therefore thought it timely to lay before the Society the principles by which, during a period of some 20 years, we have been guided in determining the suitability of waters for dietetic purposes so far only as the question of the presence or absence of sewage is concerned.

To attain our object it is plainly necessary in the first place to ascertain the composition of sewage, and from the data obtained to select those which are specially characteristic of it, and which are likely to give the best indication of the pollution of waters. It is obvious that the free or saline and the albuminoid ammonia are ingredients of the first importance, and we are also inclined to place nitric nitrogen or nitrates in the same category, although of course these can only be derivatives of sewage. Of subsidiary importance is the amount of oxygen absorbed from permanganate of potassium, and of less value still is the proportion of chlorine. Before proceeding with remarks on these data, we would draw attention to the accompanying table, which contains various analyses of waters polluted and unpolluted, and which will be necessary for reference as we proceed.

TABLE I.

ANALYSIS OF VARIOUS SAMPLES OF WATER, THE RESULTS BEING STATED IN GRAINS PER GALLON.

	1	2	3	4	5	6	7	8	9	10	11
Free ammonia.....	0.002	0.002	0.002	0.008	0.012	0.020	Neg.	0.001	0.005	0.004	0.028

Ratio of oxygen absorbed to albuminoid ammonia = 1.....	9.5	8.0	8.2	12.6	18.5	13.8	14.4	11.9	2.1	4.0	..
Chlorine.....	1.53	..	1.85	2.86	4.30	..	0.52	1.68	1.2	7.80	..
Average sewage, per cent.....	..	..	..	..	..	..	..	..	10.0	64.7	..

NOTE.—The free ammonia originally present is the actual free ammonia found and the equivalent of the ammonia which has been added together.

In considering the data referred to, it will be well to take the free and albuminoid ammonia together.

*Free and Albuminoid Ammonia.*—It may be as well to explain here that Wanklyn's albuminoid ammonia determination has been selected in preference to Frankland's organic nitrogen estimation, simply because the former is

so much more easy of manipulation than the latter, and although it does not give absolute results, yet they are decidedly reliable for the purpose in view.

Undoubtedly the quantities and relative proportions of the free and albuminoid ammonia are the data which are of greatest value in determining the presence or absence of

sewage, but, so far as we can gather, no good estimate of these has been published. The best estimate of the maximum, minimum, and average strength of sewage as regards free and albuminoid ammonia was made for the late Dr. Wallace, who obtained samples from the Glasgow sanitary inspector. These were taken every hour between 6 a.m. and 11 p.m. simultaneously from a sewer in the eastern district and from another on the south side of Glasgow. Each of these 36 samples was analysed separately, and in the following table will be found the maximum and minimum free ammonia, along with the albuminoid ammonia in the same samples, and the maximum and minimum albuminoid ammonia as well as the free ammonia in these particular samples, all the results being recorded in grains per gallon.

TABLE II.

FREE AND ALBUMINOID AMMONIA IN SEWAGE, showing the Maximum and Minimum in Grains per Gallon.

Glasgow.	Maximum Free Ammonia.	Minimum Free Ammonia.	Maximum Albuminoid Ammonia.	Minimum Albuminoid Ammonia.
East End:—				
Free ammonia	9.300	1.550	5.400	4.480
Albuminoid ammonia.	0.240	0.266	0.686	0.154
South Side:—				
Free ammonia	8.480	2.856	4.900	3.640
Albuminoid ammonia.	0.210	0.210	0.630	0.182

Besides expressing these facts, it will be well to give the average composition of the sewage of each district, and from that deduce the average of Glasgow sewage, and these are recorded in the following table:—

TABLE III.

AVERAGE COMPOSITION OF GLASGOW SEWAGE.

	Average of Sewage for entire Day from East End of Glasgow.	Average of Sewage for entire Day from South Side of Glasgow.	Average for Glasgow Sewage.
Free ammonia .....	5.190	4.960	5.07
Albuminoid ammonia ..	0.327	0.333	0.33

Other useful data which may be drawn from these results are the highest, lowest, and average proportion of free to albuminoid ammonia in individual samples, and these may be stated as follows, taking one part of albuminoid ammonia as a fixed quantity:—

	Maximum Proportion.	Minimum Proportion.	Average Proportion.
Free ammonia .....	40	6	16
Albuminoid ammonia ..	1	1	1

More recently we have analysed various samples of Glasgow sewage, and the results so far corroborate those recorded. Thus, a water contaminated with sewage ought to have on an average about 16 times as much free as albuminoid ammonia, provided it has not undergone nitrification and does not contain vegetable matter in solution. Practically the same view is held by Mr. Stoddart, but the fact has been lost sight of by some chemists who have depended too much upon a single item of analysis which

appears to point to contamination, whereas it might not do so if all the items had their due weight attached to them. Our contention, then, is that the quantities of free and albuminoid ammonia, and the ratio of these to each other in a water which has not been subjected to nitrification, are the chief rational measures of the pollution of waters with sewage. Once the presence of sewage is proved, its proportion in the water may be calculated from the grains per gallon of free ammonia, taking 5 grains per gallon as representing 100 per cent. of average sewage. Thus, for instance, a water containing 0.05 grain per gallon of free ammonia will represent a contamination of the water with 1 per cent. of average sewage.

At this point the questions arise, what ratio do the free and albuminoid ammonia bear to each other in waters not containing any animal organic matter, but only vegetable or mossy matter in solution? And how much free and albuminoid ammonia are we to regard as naturally present in unpolluted waters? In Table I. will be found the analyses of six pure natural waters, which have not undergone any appreciable nitrification, and in which the proportion of organic matter of vegetable origin varies from one of the lowest we have observed in No. 1 to the highest in Nos. 5 and 6. These have been selected as representative specimens of hundreds of analyses of waters from different localities, with the view of showing the range of purity as regards mossy matter that may be expected in natural waters uncontaminated with sewage. From an examination of these results it is apparent that the albuminoid is in every case in excess of the free ammonia, varying in the proportion of 1.4 to 4.5 of the former to 1 of the latter. It will thus be seen that there is an essential difference in the ratio between the two ammonias according as they are derived from animal or vegetable matters. In fact it may be taken as a general rule that when the organic matter present is purely of vegetable origin the albuminoid exceeds the free ammonia in amount, but we do not insist that this holds good in all cases, although it is exceptional to find it otherwise. The second question has reference to the absolute amount of free ammonia which may be allowed in a water, and our experience points to 0.01 or at most 0.012 grain per gallon if the albuminoid ammonia does not exceed that figure. When the water, however, is of a more mossy character, the albuminoid ammonia is naturally higher, and we have found that the free ammonia also increases in such cases even up to 0.02 grain per gallon, and, as far as our observation goes, invariably more albuminoid ammonia, an example of which is given in No. 6 analysis on Table I. These figures are based upon many hundreds of analyses of waters, mostly from different districts, made by us, and by going more carefully into about 400 samples analysed during the last two or three years, we find that about 66 per cent. come within these somewhat stringent limits stated, and even 58 per cent. pass the lower of these limits, thus showing how pure it is possible to get waters. These results indeed seem to be inconsistent with the idea that rain water gathers any appreciable quantity of ammonia unless it has been collected from sooty and otherwise dirty roofs.

It should be pointed out here that there is a decided peculiarity about chalybeate waters as regards the presence of free ammonia, which is higher than usual, and also bears a high proportion to the albuminoid ammonia, as will be seen by reference to analysis No. 11 on Table I. This is not a solitary instance, but we have found the same repeatedly in samples from deep bores in which it was said there could not possibly be any sewage contamination. In one particular sample, of which we do not know the source, and which contained 0.38 grain per gallon of iron in solution, there was found 0.448 grain of free and 0.042 of albuminoid ammonia. In another sample which was obtained from South America there was no less than 3 grains, each of free and albuminoid ammonia per gallon, accompanied with 13 grains of iron in solution. It is almost impossible to assign a good reason for the presence of these large quantities of ammonia unless by the presence of animal matter, but there is without doubt a peculiarity about chalybeate waters, however it may be accounted for, inasmuch as they contain sensibly more ammonia than ordinary unpolluted waters.

**Nitrates and Nitrites.** It is scarcely necessary at this point to go over again the arguments for including nitrates and nitrites as factors in judging of sewage contamination, as this has been done so recently by Mr. Stoddart, who has also demonstrated the rapidity of the oxidation of ammonia by filtration through soil. This we also observed some years ago in the case of a sewer which was leaking, and after the sewage had got mixed with more water and passed through a few feet of soil the 0.7 grain per gallon of ammonia it contained was almost entirely converted into nitrates and nitrites. This rapid nitrification can no longer be denied, nor can the fact of the danger of contracting disease from even almost perfectly oxidised sewage water, of which several cases are now on record. One very important case has been described by Dr. Milroy in his excellent paper entitled "How Typhoid Fever Spreads." He there shows how typhoid fever appeared in Fergushill and Bensley, villages near Kilwinning, and continued there for eight years, or so long as the people were allowed to drink waters containing only 0.002 grain of free and 0.003 grain of albuminoid ammonia per gallon, but at the same time they contained 2.75 grains of nitric anhydride, being condemned by Dr. Clark. In the face of such facts it is quite wrong to persist in ignoring nitrates and nitrites, or to fix a limit of 0.77 grain per gallon of nitric anhydride, as even Mr. Stoddart seems reluctantly to do. In judging the analysis of water it is a great mistake to allow the very highest proportion of nitrates and nitrites that *might possibly* be present from other sources than animal matter, and only condemn them for anything above that. It is surely more reasonable to argue as to their purity from the number of really good waters that can be obtained in comparison with the bad or suspicious ones. In the following table we give the percentages of waters of various kinds obtained from different districts:—

	Per Cent.
Unpolluted waters with less than 0.012 grain per gallon of free ammonia .....	58
Unpolluted waters containing 0.012 to 0.002 grain per gallon of free ammonia .....	8
Waters containing more than 0.002 grain per gallon of free ammonia, several known to be polluted .....	8
Waters containing under 0.77 grain per gallon of $N_2O_5$ ..	9
Waters containing 0.77 to 2.00 grain per gallon of $N_2O_5$ ..	9
Waters containing above 2 grains per gallon of $N_2O_5$ ..	8
	100

Of these waters 34 per cent. were reported as polluted with matter of the nature of sewage, and in some cases we were informed that sewage was undoubtedly getting in. There can be no valid reason for supposing that the 9 per cent. under 0.77 grain of  $N_2O_5$  per gallon are likely to be polluted with anything but sewage when we consider that two-thirds of the whole number are so very pure. In fact the probabilities seem rather to lie in the other direction. Taking everything into account, we have come to the conclusion that if the nitric anhydride found is calculated to ammonia and added to the free ammonia actually found, in order to find the free ammonia originally present, the final figure thus obtained ought not to exceed those laid down under the free and albuminoid ammonia section.

The rapid nitrification of the free ammonia in waters by simple keeping should be borne in mind. A mixture of Loch Katrine water and sewage containing over 0.3 grain of free ammonia per gallon, lost 0.04 grain per day by conversion into nitrate and nitrite. Thus, a water despatched on the one day and arriving the next might lose a comparatively large proportion of ammonia before it could be analysed. Analyses of waters containing nitrates are given in Table I., Nos. 7 and 8 being unpolluted, and 9 and 10 contaminated with sewage.

**Oxygen absorbed.**—Tidy's modification of the Forschammer oxygen process is a useful subsidiary test, which may help to throw some light on the character of a water. Our results in the waters in Table I. were calculated from experiments allowed to stand for one hour only, as there is no advantage gained for our purpose by allowing to stand for a short and a long period. If nitrites are present, the test is only valuable if they are estimated separately, but not by

permanganate, and deducted from the total result. No oxygen experiments were made with the polluted samples, but the free and albuminoid ammonia tests in the following table gives a comparison of the albuminoid ammonia and the oxygen absorbed in over 20 samples of sewage.

	Oxygen absorbed per gallon of water	Albuminoid ammonia per gallon of water
No. 1	1.27	0.10
No. 2	0.70	0.05
Average	1.06	0.08

These results show that the lowest oxygen absorbed is 2.4 times that of the albuminoid ammonia corresponding to it, the highest 8.1, and the average 4.6 times. These figures agree with the ratio of these two items in waters Nos. 9 and 10, which we found reason, in the presence of nitrates, to believe to be polluted with sewage, and which is confirmed by this test also. The difference from the ratio between the oxygen absorbed and the albuminoid ammonia in pure waters is apparent when the analyses of Nos. 1 to 8 are examined, these showing the maximum difference to be 18.5 times, the minimum 8.0 times, and the average 12.3 times more of the oxygen than the ammonia. It will be apparent, without further explanation, that these figures may also be of value in corroborating other results. It may be noted in passing that the colour of a water usually gives a fair indication of the presence of mossy matter.

**Chlorine.** The chlorine has often been insisted on as a useful proof of sewage contamination, but it is obviously of practically no value, seeing we can have pure waters varying from 0.52 to 1.3 grains per gallon of chlorine. The maximum chlorine we have found in sewage was 9.11, and the minimum 2.51, with an average of 4.92 grains per gallon. A water therefore which had got contaminated with, say, 1 per cent. of sewage would have on an average 0.05 grains per gallon added to its chlorine, and it is at once apparent that such a small quantity could never be discovered in an item which is so variable. In Table I., indeed, we have a contaminated water (No. 9) containing much less chlorine than such a pure natural water as No. 1. The very high chlorine in the grossly contaminated water No. 10 is noticeable as being probably derived from sewage, but its indication of pollution is of little value when it is impossible to miss finding it by the means which must always be applied. The estimation of chlorine for the purpose we have in view may therefore be dispensed with.

These, then, are the various points which we consider as absolutely necessary to be attended to in giving a decision on the character of a water. In many instances the evidence, based on analysis, of contamination of water by matter of the nature of sewage, is palpable, and does not require any fine discrimination; while in some cases much judgment and experience are necessary to determine the presence or otherwise of sewage impurity; and the latter remark applies not only with regard to the proportions of normal or abnormal ingredients found, but also to the ratio in which these stand to each other. But which analysts may differ along the border line, so to speak, as to whether or not certain results indicate or establish sewage contamination, there can surely be but one opinion as to the unsuitability for dietetic purposes of any water which admittedly does contain sewage matter, or even that gives evidence of previous sewage contamination, although the ammonia has practically disappeared and all its nitrogen exists as combined nitric acid, having been oxidised to its fullest limit. It by no means follows that because the dead nitrogenous matter has been fully oxidised the lethal microbe and its spores have been destroyed, and it has been noticed (as in the case brought forward by Dr. Milroy) that the clearest well waters, which are often the most palatable, are frequently responsible for the propagation of zymotic diseases. A water containing an appreciable proportion of nitrates due

originally to sewage matter may be free from objection, but that can only be either because the sewage was not infected sewage, or because the water, after receiving the impurity, has filtered through a sufficient thickness of soil, chalk, sand-stone, or other medium to ensure the absence of the minutest solid particles, such as micro-organisms and their spores. In the former case the uninfected sewage may become infected at any moment, on the outbreak of disease at its source, and in the latter case it may not be known to the analyst, and very seldom is, what natural or possibly artificial treatment the water may have received with the result of eliminating disease-producing germs. His only safe course, then, is to condemn as dangerous for dietetic use any water containing an appreciable amount of nitrates, until it is ascertained from the history of the water, confirmed, if possible, by bacteriological examination, that there is no possibility of the presence of micro-organisms of an objectionable character, and that these, even if infected sewage were percolating into the water, would always be perfectly retained by the filtering medium. Chemical analysis, therefore, is a safe and reliable guide in the question of the suitability of a water for drinking and dietetic purposes, as it will practically always detect sewage or sewage residue, and it only remains to avoid the use of such water. It is not sufficient that bacteriological examination shows the absence of pathogenic germ life in a particular sample of water, as such water might be contaminated by sewage free from disease germs, but which might become infected at any time. On the other hand, chemical analysis may fail, although rarely, to detect sewage matter or to trace it, as, for example, when all the nitrate originating from sewage nitrogen has been taken up by plants growing on soil through which the water has percolated. Then a bacteriological examination is of value, and indeed is the only means available for the determination of the suitability of the water for dietetic use. Numerous field experiments of our own have shown that rain water allowed to percolate through bare soils without vegetation dissolve in a few weeks nitrates contained in the soil amounting to several grains per gallon of the water, but that where there is vegetation growing the nitrates are entirely removed by the plants, none whatever being found in the percolate.

#### DISCUSSION.

The CHAIRMAN thought that Mr. Thomson had brought forward a subject which, to do it justice, would require a special meeting for consideration. He agreed practically with everything Mr. Thomson had said, and in reporting upon waters for many years past, he had been in the habit of relying mainly upon the data to which Mr. Thomson had referred. These data being the ammonia, the nitric acid, and the oxygen absorbed. In England much greater difficulty was experienced in valuating the results of analysis than in Scotland. That arose from the fact that in England there were deep bores, especially in the chalk strata, which contained a considerable quantity of nitrates. In Scotland there were very few, if any, deep-bore waters containing nitrates. Nearly all the waters containing nitrates were found near the surface or in very shallow wells, and practically in every case where considerable quantities of nitrates were found, they could be traced to a sewage origin. For a long time it was held by chemists that the presence of nitrates, being themselves innocuous, was no objection. It had been shown in recent years that while the nitric acid itself was not objectionable, its presence was a proof of sewage contamination or at least sewage infiltration, and, if the sewage was contaminated with any specific disease, germs of that disease were capable of multiplying in the water. As a matter of fact, a considerable number of wells which, judged by the free ammonia, or albuminoid ammonia, or the oxygen absorbed, seemed to be perfectly pure and harmless, were capable of producing specific diseases such as typhoid fever, and in these waters the only substance that could be found by analysis likely to indicate the cause of this specific disease, was the nitric acid which had been formed from the oxidation of sewage matter. Mr. Thomson had referred to a water at Kil-

winning which was reported as contaminated with sewage, and was found to be the means of propagating typhoid fever. The Cross well water at Kilmaurs was found to have communicated typhoid fever to a great many of the inhabitants. This Kilmaurs water contained free ammonia per gallon 0.001 grain, albuminoid ammonia 0.004 grain, and oxygen required 0.03 grain. These were proportions of free ammonia, albuminoid ammonia, and oxygen required, which by themselves would indicate purity; but side by side with these small quantities of ammonia and oxygen required, there was as much as 2.8 grains of nitric acid per gallon, and upon these data, basing the calculation on the presence of 5 per cent. of ammonia in average town sewage, about 17 per cent. of town sewage had been filtering into this well. In this case no attempt was made to subject the water to a bacteriological examination; but in a more recent case in a water of a different character, which contained very much more nitric acid—9.8 grains—equivalent to about 60 per cent. of oxidised town sewage, and in addition free ammonia 0.042 grain, and albuminoid ammonia 0.012 grain, on being subjected to a bacteriological examination, typhoid germs were detected. He agreed with Mr. Thomson that in judging of the character of a water there was probably nothing which gave a clearer indication, especially in a shallow well, of sewage infiltration than the presence of a considerable quantity of nitric acid. There was, however, a difficulty in laying down any particular limit above which a water might be said to be contaminated with sewage. In a country where the soil was extensively cultivated, the surface drainage of the land caused the water to contain a little nitric acid. So far as his own experience went, the amount of nitric acid in such water, even where the lands were heavily manured, seldom exceeded from 0.5 to 0.7 grain of nitric acid per gallon, and, unless where there were special reasons to indicate that this nitric acid was not from the ordinary cultivation of the land but from sewage, it could hardly be said that such a water was dangerous for domestic purposes. Where the percentage of nitric acid was appreciably greater he thought that, unless it was accountable for otherwise, there was a clear indication of sewage infiltration and consequent danger.

To the presence of chlorine in the water, he attached no importance, as the difference in the amount of chlorine was not such as would give any real indication of the quality of the water.

Regarding the amount of ammonia present in water, it must be remembered, more especially with peaty waters, that a considerable quantity of albuminoid ammonia might be found in them. In many peaty waters, such as were used for distillery purposes, there was as much as 0.04 grain per gallon of albuminoid ammonia. He did not mean to say that peaty water was good for drinking purposes, but it was certainly excellent for the production of high class whisky. Deep pit waters, especially those which contained carbonate of soda, and waters that were derived from shale strata and deep borings, frequently contained a considerable quantity of ammonia, but this ammonia was not necessarily an indication of sewage contamination and might be due to the strata.

He had occasion to examine a deep-bore water from Ayrshire, intended to supply a town, and it contained so much free or saline ammonia that, under ordinary circumstances, it would have been described as highly contaminated, but there was no sewage in the neighbourhood. He attributed the ammonia present to the shale strata.

The PRESIDENT understood Mr. Thomson to differentiate between organic matter from an animal and from a vegetable origin, although he did not quite gather the way in which the difference was proved.

He did not quite agree as to the absolute connection between "previous sewage contamination" and nitrates, and could not help thinking that the words "previous sewage contamination" in connection with nitrates had done a great deal of harm. He would certainly have looked upon the presence of nitrates as being an element of change and as dangerous in water. No doubt in shallow wells the nitrates could only come from one source, but he remembered

examining a water which came from a bore in the lower chalk about 500 feet deep, which contained 4 grains of nitrates to the gallon. It was absolutely free from organic matter and was delightful water to drink. Now, who could prove that these nitrates were derived from "previous sewage contamination"? The Chairman, when he found chloride of ammonium in water in undue proportion, did not put it down to previous sewage contamination. He very properly thought that it must have been derived from the strata. Why should not the nitrates in the deep well water be derived from the same source?

Professor HENDERSON desired to thank Mr. Thomson for having had the boldness to fix a standard, or at any rate what he believed to be a standard, of purity for water. He spoke with the utmost diffidence in the presence of experts in water analysis, but his experience was that anyone, other than an expert, had considerable difficulty in determining from the results of his analysis the suitability of waters for domestic use; for, if he referred to the standard writers on the subject, he found generally that the information he obtained contributed rather to increase his perplexity than to remove it. He wished that water experts could come to some agreement on the subject, or could at least agree to differ in an intelligible way. He observed that Mr. Thomson had discarded the determination of the ratio of organic carbon to organic nitrogen, on which Frankland laid so much stress, and he wished to know if Mr. Thomson had any reason for this, other than the desire to simplify the experimental work. As regards the occurrence of nitrates in water, it seemed to him that it was not necessary to conclude that this indicated "previous sewage contamination," because it was perhaps possible that nitrates might be formed directly from atmospheric nitrogen. He was under the impression that he had recently seen it stated that an observer had succeeded in isolating a micro-organism which possessed this power, and would be glad to know if this observation had been confirmed.

Mr. TARLOCK said that the principal point in connection with the paper was the fact that it was necessary to insist upon the nitrates present in water being interpreted as indicative of sewage contamination, unless there was information to the contrary. Whether the nitrates were of animal origin or not was a matter of some importance, but when a chemist received a sample for analysis, he did not know anything regarding its history. It was, for example, possible to suppose that the nitrates in the deep chalk waters had originated in other ways than from animal matter; but most probably they were derived from antediluvian animal matter which had got converted into nitrates.

In the case of Altona, it was clearly shown that mechanical means were quite capable of dealing with contaminated water. So long as the filters were in good order, cases of cholera diminished day by day, but on some accident happening to the filters, a fresh outbreak of the disease at once occurred.

So much recent evidence had been brought forward with regard to the presence of nitrates, indicating, if not recent, at least, previous sewage contamination, that he was surprised that any waters should be classed as pure which had not been thoroughly filtered through chalk soil or other medium sufficient to remove pathogenic germs. He thought the proper course to adopt was to report such waters as risky or dangerous—not necessarily as unfit—but as dangerous. A water might be unfit or it might be dangerous where the source of the nitrate was unknown, but might be perfectly fit if filtered sufficiently to exclude all germ contamination.

Mr. THOMSON, while he differentiated between animal matter and vegetable matter, did not mean to say that this problem was solved. The methods employed of estimating the oxygen absorbed and the albuminoid ammonia gave some indication, especially when the other results were taken into consideration, whether the organic matter was due to vegetable or animal origin matter.

The President thought Mr. Thomson's method was more likely to solve the problem than Frankland's method of comparing the carbon and the nitrogen.

Mr. THOMSON, continuing, said that the oxygen absorbed in one experiment was 8.1 times as much as the albuminoid ammonia in sewage, and with the vegetable matter in one instance the same relationship was apparent, so that they crossed each other. The composition of sewage showed that its organic matter was not of purely animal origin. Some of the sewage analysed by Mr. Wallace contained a large amount of vegetable matter, particularly about 12 or 1 o'clock in the day, when the washings of vegetables were present in large quantities. These could not be actual results from animal matter alone, for they must always include vegetable matter. It might be possible to differentiate between pure vegetable and pure animal matter, but they could not differentiate with the same reliability between the organic matter of sewage, which is a mixture of animal and vegetable, and organic matter of purely vegetable origin. There were two microbes said to be in existence, the one producing nitrates and the other producing nitrites, and the one might not be a stage of the other.

The President: Was it not the case that the nitrate-microbe only acted upon nitrite?

Mr. THOMSON doubted this. Warrington, though his opinion was not expressed in a way quite free from ambiguity, seemed to think that nitrates could be formed without the intermediate production of nitrites.

Mr. HENDERSON: Warrington's American Dictionary definitely stated that the nitrate organism only acted on the products of the nitrite one, and would not act upon anything but the nitrite.

Mr. THOMSON said the article he referred to was published about two years ago by Warrington in Thorpe's Dictionary of Applied Chemistry (Vol. II. page 699).

Mr. HENDERSON: Both organisms had been isolated and cultivated in the pure state.

The President: One would produce the nitrite and the other only the nitrate from the nitrate.

#### POSTPONED DISCUSSION ON "THE PRODUCTION OF OIL-GAS FROM PARAFFIN OILS AND FROM PURE MEMBERS OF THE PARAFFIN AND TERPENE SERIES OF HYDROCARBONS." (This Journal, 1894, p. 231-237.)

Mr. BENBY thought that it would add to the value of an investigation such as this if the elements of time, temperature, and heating surface were so clearly discriminated that it would be easy to give each its due value; so that it might be possible in each experiment to say not only the temperature to which the oil vapour had been exposed, but also the time during which the exposure had lasted.

Dr. T. R. MARSHALL inquired regarding the destructive distillation of Ozokerite, as that substance was one of considerable commercial importance.

Mr. FARWELL considered that the greatest drawback to oil-gas was its tendency to condense in the mains. The illuminating power was considerably lowered after the passage of the gas from the works through the mains to the place of consumption. By introducing a percentage of oxygen the gas was found not to condense, but to retain its illuminating value. Had Mr. Teich conducted any experiments such as would bear on this point?

Mr. Töcher, in reply, said, oil gas had been spoken of as being unstable, but as a matter of fact that was erroneous. On subjecting properly made oil-gas and coal-gas to the same variations in temperature, condensation was less from oil-gas than from coal-gas. He had not experimented with mixtures of oil-gas and oxygen although he at one time thought of doing so. Dr. Thorne claimed for oxy oil gas a greater enrichment figure than for oil-gas, while Professor Lewes and others said that equally as good results could be obtained by using oil-gas alone as an enricher. Oil-gas, when used as an enricher, showed an enrichment figure far in excess of its actual illuminating power, no matter what method was employed to manufacture the gas.

The enrichment values of mixtures of oil-gas (15–20 per cent.) and coal-gas (80–85 per cent.) had been repeatedly determined. Beyond this he was not aware of any other researches having been conducted, and it had therefore occurred to him to determine the intrinsic illuminating value of oil-gas in proportions varying from 5 to 75 per cent. The enrichment figure for oil-gas increased as the percentage taken decreased, until 118 candles were reached, equivalent to an increase of about one candle per cent. of oil-gas taken. The destructive distillation of Scotch oils was undertaken in order to determine the products of decomposition at various degrees of temperature. Professor Lewes had given the results of carefully-conducted experiments on the cracking of petroleum, and all were familiar with the valuable work done by Dr. S. Macadam on Scotch oils. Continuing, Mr. Töcher explained that his experiments, as embodied in Table I., might be considered as supplementary to those hitherto published and to determine with more precision the function which temperature played in the manufacture of gas from paraffin oils. Gas engineers had at their disposal two systems of oil-gas manufacture: (1) the cracking up of the oil at a moderately high temperature and in one operation, with the formation of about 10 to 15 per cent. of tar, and (2) the cracking up of the oil at a low temperature and subsequent re-cracking of tarry matter formed together with undecomposed oil, the ultimate products being gas and coke. The latter was the principle of Mr. Young's process, and although Mr. Young claimed that the small ratio of square surface and consequent greater free space in his retorts were important factors, still it was evident that the value of Mr. Young's process lay in the fact of its being very economical owing to the low temperature employed and to the complete conversion of the oil into gas and coke. A wide retort was preferable to a narrow one because it prevented the roasting of newly-formed gases, and for the same reason the use of iron filings or coke ought to be avoided. He quite agreed with Mr. Beilby that the principal affecting oil-gas manufacture were by no means fully understood and that there was ample field for further investigation. In instituting comparisons between, and making experiments with, retorts of various length and surface ratios, and in dealing with different rates of flow, he had endeavoured to combine the various factors in the production of oil-gas, as he thought too much stress had been hitherto laid on the question of free space alone. In the experiment with mineral oil (0.884), where he had expressed the decomposition of the oil in the form of an equation, the results would be very similar, no matter whether a Young, Patterson, or Pintsch retort were used, as the rate of flow would of course be regulated to the capacity of the retort. He had not conducted any experiments with Ozokerite, but, being an olefine, it ought to yield, on destructive distillation, a very rich gas. Being a solid hydrocarbon, there would be some difficulty in using it on a practical scale.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*Refrigerating Apparatus.* C. Linde. J. Soc. Arts. 42 (1894), 322–330.

THE author introduces his subject by describing the method used by Prof. Dewar in liquefying oxygen and air. Carbonic acid is allowed to pass from a drum into a vessel (Fig. 1) in which atmospheric pressure is maintained.

The carbonic acid boils at  $-80^{\circ}\text{C}$ . ( $-112^{\circ}\text{F}$ .). Ethylene vapour is compressed into a second vessel placed inside the first; it liquefies and is then allowed to enter a third vessel

\* Any of these specifications may be obtained by post by remitting *sd.*—the price now fixed for all specifications, postage included—to Sir Henry Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

under atmospheric pressure. The ethylene boils at about  $-100^{\circ}\text{C}.$  ( $-141^{\circ}\text{F}.$ ). At a lower pressure the ethylene would boil at  $-140^{\circ}\text{C}.$  ( $-220^{\circ}\text{F}.$ ). If oxygen be compressed into a closed vessel placed within the ethylene vessel, it is liquefied, boiling under atmospheric pressure at  $-180^{\circ}\text{C}.$  ( $-290^{\circ}\text{F}.$ ); by reducing this pressure, the temperature can be lowered to  $-200^{\circ}\text{C}.$  ( $-328^{\circ}\text{F}.$ ) at which atmospheric air condenses. Although methods are thus available for producing and maintaining temperatures not far distant from the absolute zero, the lowest temperature hitherto employed for industrial purposes is  $-110^{\circ}\text{C}.$  ( $-166^{\circ}\text{F}.$ ) which has been used for obtaining very volatile organic substances in a state of purity. The author proceeds to consider what efficiency is obtainable; what working processes are the best; and what is the position of existing machines with reference to these considerations. He compares the action of a cold-producing machine to that of a pumping-engine (Fig. 2), which has to keep water in a

Fig. 2.

shaft at a certain level by raising all the in-flowing water to a height from which it may flow away. Thermo-dynamic reasoning shows that in a perfect engine—

$$AW = \frac{H}{T} (T' - T) \dots \dots \dots (1)$$

where  $A$  is the thermal equivalent of work,  $T$  the absolute temperature at which a certain quantity of heat  $H$  is abstracted, and  $T'$  the (higher) absolute temperature at

Fig. 3.

which a certain quantity of heat  $H$  is rejected. A working process will only enable us to attain a favourable efficiency provided that at no single point heat be abstracted at lower temperatures than those strictly determined by the given problem, and that the heat be not any higher than is absolutely necessary for its rejection by the cooling water.

Refrigerating machines may be classed in three groups. Fig. 3 exhibits the action of the first type, in which the reduction in temperature depends upon the expansion of air. The compressor draws in air from the freezing chamber and compresses it to about 3 atmospheres. The compressed air is passed through a cooler, where its temperature is reduced by cooling water. It is then admitted into an expansion cylinder, whence, after cooling by expansion, performing a certain amount of work, it re-enters the freezing chamber.

The second and third types of refrigerating machines depend upon the reduction of temperature by the evaporation of a volatile liquid, the return to the liquid state being effected either by compression or by absorption. Fig. 4 illustrates the action of a machine of the second type

Fig. 4.

(compression and evaporation). The vapour from a volatile liquid is aspirated by a compressor and forced into a condenser at a pressure corresponding to the temperature  $T'$ , at which the transfer of the latent heat to the cooling water is rendered possible. The condensed liquid returns by the regulating valve into the refrigerator. Such machines have been termed "cold steam-engines" by Zenner, as they represent simply the reversal of a steam-engine. For a perfect process the nature of the volatile liquid is quite immaterial, but in practice it is disadvantageous to employ volatile liquid possessing a critical point close to the temperature range within which the working process is performed. It has been proved that

Fig. 5.

when ammonia is used, as much as two-thirds of the heat determined by equation (1) can actually be abstracted under ordinary conditions of working.

The third type of refrigerating machine—the absorption machine—is shown in Fig. 5. Like the compression machine, it has a condenser and a refrigerator. The ammonia vapours are absorbed by a weak solution of ammonia in water; after this is saturated it is pumped into the generator, exchanging on its way its heat with that of the weak solution coming from the generator. The solution in the generator is then heated so as to drive off the ammonia, and the pressure of the vapours developed is sufficient to liquefy them in the condenser.—D. E. J.

#### PATENTS.

*Improved Combined Digester, Dryer, Washer, and Disinfecter, for Bones, Fat, Meat, Glue, and other Materials.* H. G. Warner, Wandsworth, Surrey. Eng. Pat. 6485, March 27, 1893.

AN upright boiler is provided with a steam-jacket, and fixed therein is a cylindrical perforated casing to contain the material to be treated; the boiler is also fitted with perforated ring pipes for spraying steam, hot water, or disinfecting fluid into the casing, while another pipe supplies hot air for drying. Manholes are provided for introducing and discharging the contents, and a shaft provided with vanes may be used for stirring up the contents. The apparatus may be used for digesting drying, washing, or disinfecting bones, meat, glue, clothes, or other substances.—E. G. C.

*Improvements in Apparatus for the Manufacture of Metallic Pigments or Compounds, and in the Production of Lead and Zinc Pigments or Compounds and Combinations of these, by means of such Apparatus.* A. C. J. Charlier, Glasgow. Eng. Pat. 7119, April 6, 1893.

See under XIII. A., page 532.

*Improvements in Separating Oleaginous or Fatty Matters from Boiler Feed-Water or other Water.* J. and G. Weir, Cathcart, Renfrew, North Britain. Eng. Pat. 10,664, May 31, 1893.

WITHIN a box-like casing, layers of an absorbent material are arranged, such as animal fibre, hair, sponge, or the like, with channels between each layer. The feed-water to be purified is introduced at a suitable point, and forced through tortuous channels, in which it gives up its fatty matters to the absorbent material, emerging in a purified condition. The fatty matters are removed from the absorbent material by squeezing between rollers, washing with a solvent, or by similar means. In a modified arrangement the water flows through an annular cylinder with curved guide blades, the inner surface of the annular cylinder being formed by a roll of flannel, backed by perforated sheet metal; the fatty matters are absorbed by the flannel and fall into the central

cavity of the cylinder, from which they are discharged in any suitable manner. Other modified arrangements are described and illustrated.—E. G. C.

*Improvements in Calcining Apparatus for the Conversion of Bicarbonate of Soda into Carbonate of Soda and other Uses.* La Société Marcheville Daguin and Company, Paris. (Under Internat. Convention, date claimed December 3, 1892.) Eng. Pat. 12,997, July 3, 1893.

See under VII., page 518.

*A Process for Preventing Incrustation in Steam Boilers.* V. Gane, Paris, France. Eng. Pat. 14,211, July 22, 1893.

INCRUSTATION in boilers is prevented by causing the shell to absorb petroleum, shale oil, or other hydrocarbon under pressure in the following manner. The boiler is filled with petroleum and left for some hours under pressure, when, it is said, the petroleum penetrates into the iron or steel plate and incrustation is thereby prevented from adhering. To remove the incrustation from old boilers the petroleum is introduced from above and the boiler is slowly filled with water from below, thereby causing the lighter petroleum to slowly come into contact with the porous incrustation and penetrate it; the petroleum is finally expelled at a suitable outlet at the top for use over again. The absorption of petroleum by the incrustation causes the latter to scale and fall to the bottom of the boiler, from whence it is readily removed.—E. G. C.

*An Improved Still or Apparatus for Distilling Spirits and all kinds of other Liquids.* G. Morris and W. Edney, both of Bristol. Eng. Pat. 16,063, August 25, 1893.

THE figure (see next page) is a sectional elevation of the still, which consists of a hemispherical body A, bellied or swelled out at G, with a recessed lip H. Over this body is mounted a conical dome J, having an outlet L, containing baffle-plates N, to increase the surface area of the condensed liquid which flows through. The spirit or other liquid is introduced into the bowl A by means of the orifice J<sup>1</sup>, and heat is applied by means of a steam-jacket B or other suitable contrivance. The vapour is compelled to rise centrally by means of the curved lips H K, and impinges upon the dome J, which latter is cooled by means of the stream of water passing from the water-channel O R through the chamber S. The condensed liquid flows down the sides of the dome J, and passes away between the baffle-plates N in the worm L, being cooled by the stream of water passing in the reverse direction through the annular channel O. The distilled liquid finally escapes through the pipe M. The steam-jacket has a steam-inlet C, a safety-valve D, and a condensed water outlet E, while an outlet F is provided for cleansing. The steam-jacket may be dispensed with and other suitable modes of heating used, while in large pans two or more collecting domes J may be used.—E. G. C.

*Improvements in Valves for Tar, Ammoniacal Liquor, and other Liquids.* F. S. Cripps, Sutton, Surrey. Eng. Pat. 17,737, September 21, 1893.

See under III., page 508.

AN IMPROVED STILL.

*Improved Apparatus for Filtering or Purifying Feed-water for Marine or other Steam Boilers.* J. Wotherpoon, Forest Hill, Kent, and J. Davie, Wallsend-on-Tyne. Eng. Pat. 1910, January 29, 1894.

This specification claims "the combination of a filter-body made of an open-ended, parallel-sided formation, with a depending mud-collector adjacent to each end; a stationary perforated diaphragm, fitting within such filter-body and between the mud-collectors; filtering media arranged between such diaphragms; covers adapted to close the ends of the filter-body and to limit the outward position of such diaphragms," &c. The parts are forced together by means of a movable back-plate actuated by a hand-wheel and screw, so as to force the collected impurities into the mud- or sediment-collectors, from which they are discharged through mud-cocks. The water to be filtered is supplied to one end of the filter-chamber and forced through the layers of filtering media, issuing by a pipe which leads to the boiler.—E. G. C.

are: (1)  $C_2H_4 = C_2 + 2H_2$  when the decomposition takes place at a very high temperature; and (2)  $C_2H_4 = C + CH_4$  at a lower temperature. According to Day, at about 350° condensation without breaking up only occurs; whilst at 400°, after a sufficiently long time, entire decomposition is brought about, with formation of marsh-gas, ethane, and liquid products. The author prepared ethylene from rectified methylated spirit and strong sulphuric acid (25 parts to 150 respectively), and stored it over alkaline pyrogallate solution; so that the gas used contained 98·80 per cent. of ethylene and 1·20 of nitrogen. After heating for 100 hours to 400° C. the composition was as follows, a little air having obviously been admitted:—

Carbon dioxide, 0·82; free oxygen, nil; unsaturated hydrocarbons, 7·00; saturated hydrocarbons, 61·82; carbon monoxide, 1·17; hydrogen, 22·18; nitrogen, 7·01; total, 100·00.

In analysing such a mixture, after removal of  $CO_2$  by sodium hydrate and oxygen by alkaline pyrogallate, the unsaturated hydrocarbons are absorbed by a solution of bromine in potassium bromide, and the  $CO$  by acid cuprous chloride. The residue, on agitation with petroleum, is deprived of most of the saturated hydrocarbons, the residual portion thereof, chiefly marsh-gas, being determined by explosion and  $CO_2$  absorption (see this Journal, 1891, 107). If the saturated hydrocarbons be not treated with petroleum before explosion, the quantity of  $CO_2$  formed on combustion exceeds 100 per cent. of the combustible gas acted upon, showing that higher homologues of marsh gas, especially ethane, are present.

On passing ethylene through a platinum tube heated to from 600° to 1,500° C. (temperature ascertained by Le Chatelier's thermo-couple, platinum and platinum-

## II.—FUEL, GAS, AND LIGHT.

*The Action of Heat on Ethylene.* V. B. Lewes. Proc. Roy. Soc. 55, 90—107.

FROM the work of earlier observers the reactions accepted in the text-books as those occurring when ethylene is heated

rhodium), it was found that the decomposition produced varied with the temperature and rate of flow: thus, with a

particular tube and current of about 10 cc. per minute, the following figures were obtained:—

Temperature—centigrade.	600°	700°	800°	900°	1,000°	1,200°	1,500°
Percentage of ethylene in gas used.	96.78	96.73	96.78	94.8	94.8	98.91	98.91

#### ANALYSIS OF GAS AFTER HEATING: PER CENT.

Unsaturated hydrocarbons.	96.42	96.39	96.46	94.77	18.02	10.54	0.43
Containing acetylene..	0	0	Trace	0.82	0.60	3.60	0
Saturated hydrocarbons.	0	0	0	59.73	76.48	55.26	27.80
Hydrogen.....	0	0	0	0	0	25.11	62.68

#### CARBON DEPOSITED AND OIL FORMED IN GRMS. PER 100 CC.

Carbon.....	0	0	0	0	0	0.0273	Large quantity
Oil.....	0	0	0	0.0024	0.0048	0.0038	0
Change of volume.....	0	0	0	Decrease	Decrease	Increase	Large increase

When the rate of flow was reduced to less than one-half (4.2 cc. per minute), a higher member of the paraffin series, probably ethane, was formed at temperatures up to 900°, with but little methane; at 1,000° the quantity of the former diminished, and that of the latter increased; and at 1,200°, little but methane was formed; accordingly a series of observations was made by passing ethane through the hot tube, the gas being prepared from ethyl iodide by the copper-zinc couple in presence of water, and containing 96.38 per cent. of actual ethane. The following figures were obtained:—

Temperature.....	900°	1,000°	1,200°	1,500°
Unsaturated hydrocarbons produced.	31.00	28.42	11.58	1.69
Containing acetylene.....	Trace	0.30	1.80	0.91
Saturated hydrocarbons—				
Paraffin.....	12.82	8.34	3.88	0
Methane.....	12.01	12.73	21.83	20.62
Hydrogen.....	49.64	46.78	57.45	73.35
Carbon formed per 100 cc. of gas.	0	0	0.0126	0.0314
Oil formed per 100 cc. of gas.	0	Trace	Trace	0

Hence, even below 900° C., ethane decomposes with liberation of hydrogen and formation of unsaturated hydrocarbons, chiefly ethylene, which latter is decomposed as before at higher temperatures; accordingly, the text-book equation No. 2 (*already given*) is incorrect; carbon and hydrogen appear simultaneously, and are probably both derived from acetylene.

On passing acetylene through the tube heated to 1,000°, it was found that about a quarter remained unchanged, the remainder chiefly becoming polymerised to benzene; a little ethylene was formed, probably by direct combination of part of the acetylene with hydrogen liberated by the decomposition of another portion. On the other hand, on passing a mixture of 3 vols. hydrogen and 1 of ethylene through the tube at 1,250°, the quantity of acetylene produced was somewhat larger than when ethylene not mixed with hydrogen was used.

Methane was prepared from methyl iodide by means of the copper-zinc couple and water (gas contained 99.2 per

cent. of methane); on passing through the hot tube the following results were obtained:—

Temperature Centigrade ...	1,000°	1,200°	1,500°	1,500°
Unsaturated hydrocarbons produced.	Trace.	0.07	0.39	1.20
Containing acetylene.....	Trace.	0.07	0.39	0.96
Saturated hydrocarbons....	37.65	90.00	88.52	19.22
Hydrogen.....	1.55	8.53	10.37	78.66
Carbon deposited per 100 cc. of gas.	0	0	Trace.	0.015
Oil formed per 100 cc. of gas.	0.0023	0.0025	0.0005	0

Hence methane is much more stable under the influence of heat than any of the other gaseous hydrocarbons examined; it probably decomposes first into acetylene and hydrogen, thus:—

and then the acetylene either polymerises or decomposes into carbon and hydrogen, according to the temperature. These results explain why the flame of methane, when burning at an open tube, is practically non-luminous, the maximum temperature of the flame being below 1,100° C., so that no acetylene is formed; whilst, when burnt in a regenerative burner at 1,500°, the light emitted is of considerable illuminating value.

A mixture of hydrogen and benzene vapour (5.28 per cent. benzene) gave the following results on passing through the tube:—

Temperature Centigrade.....	900°	1,100°	1,300°
Unsaturated hydrocarbons produced	5.00	3.33	2.43
Containing acetylene.....	0	Trace	0.083
Saturated hydrocarbons.....	0	2.87	5.62
Hydrogen.....	95.00	93.80	92.47
Carbon deposited per 100 cc. of gas	0	Trace	0.01
Oil deposited per 100 cc. of gas....	Trace	0.012	0

Hence the diluted benzene breaks down to acetylene, methane, and carbon, and finally to carbon and hydrogen.

On the whole, the conclusion drawn from the various series of experiments is that the primary action of heat upon ethylene is represented by the equation

whilst the final decomposition is, as represented by previous observers, —

In between, a variety of reactions occur, owing to the polymerisation of the acetylene thus formed from the ethylene, and also at higher temperatures from the methane, according to the equation—

—C. R. A. W.

*A Process and Appliance for Electrically treating Gaseous and other Bodies, a New Compound Gas made by such Process, and Apparatus for Producing and Consuming said Gaseous Product.* T. G. Hall, Chicago, county of Cook, U.S.A. Eng. Pat. 6551, March 23, 1893.

See under XI., page 528.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*The Sulphur Compounds in Ohio Petroleum.* Charles F. Mabery and Albert W. Smith. Amer. Chem. Jour. 16 [2], 83—89.

In this paper the authors respond to the adverse criticism of Kast and Lagai (Dingler's polyt. Journal, 284, 69; this Journal, 1892, 598), upon their former work (Amer. Chem. Jour. 13, 232; this Journal, 1891, 629, and 1890, 275).

The authors continue to have reliance in the Carius method of determining sulphur if thoughtfully carried out, sealed tubes being employed; and certainly they prefer it to that employed by Kast and Lagai, involving, as this latter is said to do, an oxidation of explosively-decomposable sulphur compounds with fuming nitric acid and potassium chlorate in an open dish. Further to test the Carius' method, analyses of pure ethyl sulphide have been made by it and S determined, 35.46 and 35.48, against calculated quantity, 35.55. Again, a crude burning oil distillate gave by Carius' method 0.46 per cent. S, while, by ignition with soda-lime, 0.40 per cent. was obtained.

With regard to the lead and calcium salts obtainable by neutralising the sulphuric acid solution of the sulphur-containing bodies, which is produced in commercial refining, it is admitted by both sets of observers that these are not salts of sulpho acids derived from the paraffin alkyl sulphides dissolved in the acid; but that, whilst these latter are present and are obtainable by dilution of the concentrated acid liquor, there are other sulphur-containing bodies in sulphur-petroleum which are capable of forming salts.

Messrs. Kast and Lagai were unable to obtain the definite crystalline compounds with mercuric chloride; the authors now describe at some length two of them, derived from the "crude naphtha distillate" of Findlay crude petroleum and from the "crude burning oil distillate" of Lima petroleum respectively.

The crystalline bodies are obtained by precipitation of the oil with aqueous solution of mercuric chloride, filtration, washing with gasoline, pressing, and drying in the air. They are decomposed by treatment with alcoholic solution of sodium sulphide or by hydrogen sulphide, yielding oils

(the distillation of which is described) containing 49.72 per cent. and 47.68 per cent. of sulphur respectively. From 800 grms. of Findlay distillate 70 grms. of the mercury compound were obtained.

The authors do not agree with Kast and Lagai that the odour of the crude oils is due solely to unsaturated hydrocarbons; on the contrary, they consider they have afforded grounds—by the separation of "several classes" of odorous substances, not otherwise specified, however—for the statements that it is due to "a mixture of bad-smelling compounds." They state that, while the crude distillates may be completely deodorised by mercuric chloride, only about two-thirds of the S-containing bodies are so removed in the case of Ohio petroleum, and about two-fifths in the case of a distillate from Canadian petroleum. Kast and Lagai state that sulphur oils may be deodorised by sulphuric acid, one-quarter only of the sulphur-containing bodies being removed, and this result appears to be confirmed by the author, as to the amount of the bodies removed, though the deodorisation was not quite so perfect.

It is noteworthy that the Ohio oil used by Kast and Lagai was obtained in Bremen and contained 1 per cent. of sulphur; the authors state that Ohio oil never contains more than 0.6 per cent., and quote in their support Prof. Orton and Lord (U.S. Geological Survey, eighth annual report), who found 0.553 per cent. S in crude Trenton limestone oil; other analysts, who report about 0.5 per cent.; and the experience of commercial manufacture, which indicates on the average 0.55 per cent.

Canadian sulphur petroleum contains more sulphur than do the Ohio petroleum.—L. R. B.

*Preliminary Examination of Canadian Sulphur-Petroleum.* Charles F. Mabery. Amer. Chem. Jour. 16 [2], 89-93.

THE author is engaged upon a comprehensive study of this subject, but publishes the pre-ent preliminary notice, as he has found that Kast and Lagai are also working in the same field.

The material investigated was the "sludge acid" obtained in refining the burning oil distillate of a crude Canadian petroleum. This crude oil had a specific gravity of 0.86 at 20°, and contained 0.98 per cent. of sulphur, exclusive of a further quantity present as hydrogen sulphide. Upon distillation, under a tension of 250 mm., 11 per cent. by weight was collected below 150°, 24 per cent. between 150° and 300°, and the residue amounted to 65 per cent. These three fractions contained respectively 0.195 per cent., 0.64 per cent., and 0.98 per cent. of sulphur.

The "sulphur oil" held in solution in the "sludge acid" was precipitated by the addition of the acid to water, and, after washing, measured half the bulk of the "sludge acid" used. It had a specific gravity of 0.86 at 15°, was dark brown in colour, and contained 9.94 per cent. of S. Distillation with steam (unattended by serious decomposition) gave a distillate with a powerful odour, containing 5.46 per cent. of S, while the residue contained 10.41 per cent. The distillate redistilled below 200° and had sp. gr. 0.82 at 20°. Further fractionation was attended with great difficulty owing to the peculiar persistency with which water was retained, and in some cases decomposition with separation of sulphur, occurred. However, the steam distillate was redistilled six times (tension = 150 mm.); the fractions, the weights of which are not given, contained sulphur as follows: fraction, 32—40° (0.13 per cent.); 40—70° (0.65 per cent.); 110°—120° (11.51 per cent.); 120—130° (13.94 per cent.); 140°—150° (13.44 per cent.); 160—170° (13.93 per cent.). Each fraction reacted with bromine, leaving no residual oil. The lower fractions were united with hydrobromic acid and polymerised upon standing, in one case noted, with rise in temperature of 150°. The fractions are regarded as composed of unsaturated hydrocarbons, and the  $C_{12}H_{22}$  hydrocarbons are considered to be absent.

The residue of the steam distillation was similarly fractionated, but the sulphur contents of only the 65—72° and 96°—97° fractions were recorded, being 9.12 per cent. and 12.96 per cent. respectively. All the fractions gave

crystalline or viscous precipitates with mercuric chloride, leaving oils with intensely penetrating odours.

The author has now resumed the investigation upon a much larger scale, but finds that the "sulphur oil" he now obtains, unlike the parallel product he formerly obtained from the refinery, undergoes decomposition during steam-distillation, with production of hydrogen sulphide, sulphur, sulphuric and sulphurous acids. Decomposition is also induced by the presence of air. He now therefore dries the "sulphur oil" as far as possible, by letting it stand for a week over recently-fused calcium chloride, and then distils (under tension of 15 mm.) in a porcelain still and gets but little decomposition.

It is interesting to note that, as in the former case, great difficulty is experienced in separating water from the oil: after long standing, 15 litres still contain about 10 cc. of water.

With the large quantities of material now being worked the author expects to be able definitely to isolate all the various odorous bodies which have been met with.

—E. R. B.

#### PATENTS.

*Improvements in obtaining Sulphonic Acids and Sulphone-like Compounds, Free from Inorganic Salts, from the Neutralised Product of the Action of Sulphuric Acid upon Mineral and similar Oils, and particularly Hydrocarbons, Artificially or Naturally Sulphuretted.* L. O. Helmers, Hamburg. Eng. Pat. 6044, March 21, 1893.

THE methods in use for purifying the sulphonated compounds produced as above are unsatisfactory, that consisting in dissolving the sulphonised product in water and separating by the addition of a salt (Eng. Pat. 10,523, July 24, 1884) yielding an impure result, while dialysis entails a loss of the sulphonic acids or their salts. The improved methods described consist in the employment of alcohol and chloroform, singly or together, as solvents. If the neutralised sulphenised product, freed as much as possible from water, be treated with strong alcohol (ethylic or other alcohols), the sulphonic acid salts will be dissolved out, leaving a mixture of sulphones and sulphone-like bodies and inorganic salts, from which the last can be extracted by washing with water. The alcoholic extract will contain small quantities of sulphone-like bodies, which treatment with chloroform will remove. The alternative method of purification consists in treating the neutralised sulphonised product with a mixture of alcohol and chloroform (or ether, petroleum, naphtha, &c.), which dissolves out everything but the inorganic salts. By evaporating off the solvent and treating the residue with chloroform, the sulphonic bodies will be extracted, or treatment with alcohol will dissolve out the sulphonic acid compounds.—J. G. W.

*Improvements in Valves for Tar, Ammoniacal Liquor, and other Liquids.* F. S. Cripps, Sutton, Surrey. Eng. Pat. 17,737, September 21, 1893.

THE valve is of the ordinary rectangular slide type, working in a centre casting provided with two side flanges. These latter flanges are bolted on to the adjacent pipe flanges, having the slide casting between them, the facing strips being surfaced to form sound joints when the centre casting and side flanges are bolted together. The valve is actuated by a screw and can be locked in any position by means of lock nuts.—E. G. C.

#### IV.—COLOURING MATTERS AND DYES.

*A Japanese Ponceau-Red Dye.* Scheurer. Chem. Ind. 17 [2], 39.

THIS ponceau-red appears to consist of the crocin obtained by the decomposition of the glucoside of the saffron, at all events a red material is obtained, which in China, by some unknown method, is prepared from saffron blossoms. This raw material is dyed in an acid bath upon hemp, and then the colouring matter thus fixed is again abstracted by means of potash solutions. Probably by acidifying this solution, the Japanese red is then obtained ready for use as a paste. It is interesting to note that the weak affinity for vegetable fibres probably containing tannin, is thus made use of for the isolation and purification of the dyestuff.

—W. S.

*Diazo Compounds and Nitrosamines.* C. Schraube and C. Schmidt. Ber. 27, 514—523.

THE fact that, by the action of diazobenzene chloride upon ketones and aldehydes, hydrazones are produced, first led various investigators to the hypothesis of the capacity of diazobenzene to react in the isomeric nitrosamine form,  $C_6H_5.NH.NO$ , as well as in the diazo form,  $C_6H_5N:N.OH$ , yielding hydrazine compounds in the former case and azo compounds in the latter.

The authors have succeeded in proving not only the existence of the nitrosamine form of diazobenzene, but also in obtaining phenylnitrosamine in the shape of its stable alkaline salts. If para-nitrobenzene chloride is added to a dilute solution of caustic soda, an excess of the latter being maintained, a clear solution is obtained, without evolution of nitrogen, in which the presence of the diazo compound can no longer be shown. After a time crystals separate from this solution, especially after the addition of common salt. These crystals were found to consist of the sodium salt of para-nitrophenylnitrosamine. The free nitrosamine is separated as a sparingly soluble crystalline precipitate by the addition of an acid to the cold alkaline solution.

The supposition that the diazobenzene potassium compound first described by Griess might also be a nitrosamine derivative was, by experiment, proved to be unfounded, for it gives at once, like diazobenzene chloride, a colour reaction when brought into contact with phenols under the necessary conditions, whilst the nitrosamines do not show this property. The conversion of the diazo compound into the nitrosamine may, however, be accomplished by heating the alkaline mixture above  $100^\circ$ . The nitrosamine then separates.

Owing to the extraordinary tendency of para-nitrodiazobenzene to be at once converted into the nitrosamine, even with the most dilute solutions of alkali and at a temperature of  $16^\circ$  the potassium compound of that body could not be obtained. Another great difference exhibits itself in the behaviour of the two nitrosamine salts on the addition of an acid to their solutions. While para-nitrophenylnitrosamine is separated as a fairly stable compound, phenylnitrosamine does not appear to exist in its free state. Even with the greatest care reconversion into diazobenzene takes place immediately, and can instantaneously be completed by supersaturation with acetic acid.

A mixture of the alkaline solutions of para-nitrophenylnitrosamine and  $\beta$ -naphthol gradually produces a precipitate of a dyestuff on being warmed, or even on being allowed to stand sufficiently long in a closed vessel. When spread on paper and thus exposed to the action of the carbonic acid of the atmosphere, the formation of colouring matter from a freshly prepared mixture takes place very slowly. Phenylnitrosamine under the same conditions at once forms a colouring matter in consequence of the action of the carbonic acid, whilst no colour reaction takes place either on heating or continued standing. These facts, together with the negative results of experiments made with a view of combining phenylnitrosamine sodium in an alkaline

solution with acetone, acetoacetic acid, or acetone diacetic acid, are inconsistent with the theory of phenylhydrazine being an intermediary product in the formation of the hydrazones. —F. M.

*A Colouring Matter occurring in the Leaves of the Grape-Vine.* E. Schunck, E. Knecht, and L. Marchlewski. Ber. 27, 187-188.

THE green portions of plants contain besides chlorophyll as a rule only a yellow colouring matter, called carotin, chrysophyll, or erythrophyll, which is insoluble in water. Several investigators find, however, that some kinds of leaves give aqueous extracts of a more or less impure yellow colour, an observation which is explicable from the fact that in most of these instances mature leaves were used. Young leaves yield an almost colourless extract. Yellow autumn leaves, however, contain considerable quantities of soluble colouring matters. Thus the authors found that fallen beech and horse-chestnut leaves give deeply coloured aqueous extracts. They have also succeeded in isolating a yellow colouring matter from vine leaves, the investigation being suggested by the use of these leaves for dyeing purposes in Persia. Like most vegetable coloring matters, this substance is a glucoside. It can be prepared by the addition of lead acetate to the decoction of the finely-powdered leaves, treatment of the precipitate formed with sulphuretted hydrogen, and subsequent extraction of the dried lead sulphide with boiling alcohol. The residue, obtained by evaporation of the alcohol, is freed from sulphur by means of carbon bisulphide, the glucoside remaining as an indistinctly crystalline brownish-yellow substance. By boiling with dilute sulphuric acid it is split up into a sparingly soluble brown body and glucose. This colouring matter may, after washing with water, be purified by adding to its alcoholic solution an alcoholic solution of lead acetate and treating the previously washed and dried bluish-green precipitate with ether containing hydrochloric acid, by which the impurities are taken up. The remaining colouring matter is then dissolved in alcohol and precipitated from this solution by the addition of water. It forms a reddish-brown powder, soluble in alkalis with a brown colour. Its aqueous solution produces upon chrome-mordanted wool fine brown shades, and dyes wool mordanted with tin a fine yellow. The colouring matter may possibly be of practical value. The vine leaves were also found to contain up to 2 per cent. of potassium hydrogen tartrate. —F. M.

*Chrysin.* St. v. Kostanecki. Ber. 26, 2901-2905.

PORTULACA buds contain two yellow colouring matters, chrysin and teetochrysin. The latter is the methyl ether of the former. Piccard, the discoverer of these substances, found that chrysin possesses the formula  $C_{15}H_{10}O_2$ , and is by alkalis split up into phloroglucinol, benzoic acid, and acetic acid, a small quantity of acetophenone being formed at the same time. Chrysin forms a diacetyl derivative, and therefore must contain two free hydroxyl groups. Only one of these, however, can be replaced by methoxyl. Sodium compounds of the alkyl ethers of chrysin can be obtained by carefully adding caustic soda to their alcoholic solutions until a slight turbidity ensues. These compounds are almost insoluble even in hot water, but are split up by it into their constituents. The methyl ether forms the acetyl compound  $C_{15}H_{10}O_2 \cdot (OCH_3) \cdot (OC(=O)CH_3)$ , which crystallises from alcohol in bright, colourless needles, melting at 149°. The formula which the author arrives at as the one best representing the constitution of chrysin, shows its close relationship to the hydroxy-xanthenes, chrysin being a phenylated pheno- $\gamma$ -pyrone, and xanthone a diphen- $\gamma$ -pyrone. Fisetin and quercetin may be regarded as hydroxy-derivatives of the mother-substance of chrysin (this Journal, 1894, 381).

F. M.

## PATENTS.

*The Manufacture or Production of Dyestuffs.* H. E. Newton, London. From "The Farbentabrikeu vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 7339, April 10, 1893.

IN Eng. Pat. 13,113 of 1890 (this Journal, 1891, 760) mixed tetrazo dyestuffs are produced by combining the tetrazo derivative of a diamine with one molecular proportion of 1-1' amidonaphthol 3-3' disulphonic acid, and one molecular proportion of an amine, a phenol, naphthol, dihydroxynaphthalene or one of their sulphonic or carboxylic acids. The term amine would appear to include not only monamines of the benzene and naphthalene series, but also diamines and their sulphonic, carboxylic, or alkylated derivatives. The order in which the combinations are performed may be reversed, that is, the tetrazo compound may be first combined with the amine or phenol or a derivative thereof, and afterwards with the amidonaphthol disulphonic acid. It has now been discovered that these mixed tetrazo dyestuffs are capable of combining with another molecular proportion of a diazo or diazo-azo compound, or with half a molecular proportion of a tetrazo compound, or with one molecular proportion of an intermediate product resulting from the combination of equal molecular proportions of a tetrazo derivative of benzidine, its analogues and homologues and an amine, diamine, phenol, amidophenol, or amidophenol ether of the benzene or naphthalene series or a carboxylic or sulphonic acid thereof. A further extension of the original patent is that the amidonaphthol disulphonic acid can be replaced by other amidonaphthol sulphonic acids, such as amidonaphthol sulphonic acid G or B or the like, or by 1-3' or 1-2' naphthylamine sulphonic acid, amidonaphthol, amidonaphthol ethers, amidonaphthol ether sulphonic acids, amidonaphthoxy-acetic acids, amidonaphthoxy-acetic sulphonic acids, dihydroxynaphthalenes, or sulphonic derivatives of any of these components. The combinations obtained by any of the foregoing methods may, when insoluble, be sulphonated and thus rendered useful for dyeing purposes. Furthermore, those dyestuffs which contain diazotisable groups may be diazotised on the fibre and combined with amines, phenols, and their derivatives. The process for obtaining colouring matters described in Eng. Pat. 15,525 of 1891 (this Journal, 1892, 741), by combining one molecular proportion of a tetrazo compound with one molecular proportion of amidonaphthol disulphonic acid H, and one molecular proportion of *m*-tolylene diamine, chrysoidine, or Bismarck brown is disclaimed. The following example illustrates the general method employed in carrying out this invention. The intermediate product obtained from the tetrazo derivative from 24.4 kilos. of dianisidine and 26.2 kilos. of 1-1'-dihydroxynaphthalene sodium sulphamate is combined in an acid solution in presence of sodium acetate with 10.8 kilos. of *m*-phenylene diamine. The diazo compound from 30.3 kilos. of  $\beta$ -naphthylamine 3-3' disulphonic acid is then stirred into the liquid. After some time sodium carbonate is added and the mixture is heated, after which the dyestuff is salted out, filter-pressed, and dried. It has the following formula:—

—T. A. I.

*The Manufacture or Production of Dyestuffs.* II. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 8093, April 21, 1893.

This is an extension of Eng. Pats. 4757 and 6035 of 1893 (this Journal, 1894, 245 and 383). The alkylated *p*-phenylenediamine thiosulphonic acids and their derivatives obtained by the action of thiosulphates on the nitroso derivatives of secondary or tertiary amines, yield thiazine colouring matters when oxidised together with amidonaphthols and amidonaphthol sulphonic acids (corresponding to the *o*-nitrosonaphthols and *o*-nitrosonaphthol sulphonic acids of Eng. Pat. 6035 of 1893), and the corresponding hydroquinones and their sulphonic acids are capable of interacting in the same manner. A mixture of 25 kilos. of dimethyl-*p*-phenylene diamine thiosulphonic acid and 28 kilos. of 1-2-3'-dihydroxynaphthalene potassium sulphate is suspended in about 800 litres of water and mixed with 200 kilos. of 25 per cent. sodium hydroxide. The brownish-coloured liquid produced is heated on the water-bath and air passed through for several hours, after which it is made acid with acetic acid, when the neutral sodium salt of the dyestuff is precipitated. The dyestuff is identical with that obtained from dimethyl-*p*-phenylene diamine thiosulphonic acid and potassium  $\beta$ -naphthoquinone sulphate, and the same product is also obtained if, in place of this product, the 1-amido-2-naphthol-3'-sulphonic acid be employed. When the products obtained are sparingly soluble they may be sulphonated by treatment with fuming sulphuric acid or other suitable sulphonating agents. The specification further describes certain colouring matters of the oxazine type, of which that obtained from nitrosodimethyl-*m*-amidophenol and  $\beta$ -naphthoquinone is a typical example. It has the following constitution:—

The product dissolves with difficulty in water, and is rendered more suitable for dyeing and printing purposes by sulphonation. A sulphonated product is obtained directly by adding a concentrated solution of 28 kilos. of potassium 1-2-3'-dihydroxynaphthalene sulphate and 25 kilos. of crystallised sodium acetate to a hot solution of 23 kilos. of nitrosodiethyl-*m*-amidophenol in 700 litres of water. The liquid is then boiled and stirred continuously until a sample on cooling shows no further increase in the amount of dyestuff deposited. The whole is then allowed to cool, when the colouring matter separates out in yellowish crystals with a greenish reflex. A further quantity can be precipitated from the mother-liquor by adding salt. The colouring matter dissolves easily in hot water, and gives bright blue shades on chrome-mordanted wool fast to light and fulling. In place of the dihydroxynaphthalene sulphonic acid, the corresponding amidonaphthol sulphonic acid may be employed, the resulting product being the same, as in this case ammonia is liberated during the condensation.—T. A. L.

*The Manufacture of New Sulpho Acids of Phenyl-rosinduline and Analogues and Homologues thereof.* J. Y. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 8184, April 22, 1893.

Certain of the sulphonic acids of phenyl-rosinduline, as described in Eng. Pat. 15,259 of 1888 (this Journal, 1889, 877), are known in commerce under the name azo-carmines, and further discoveries with regard to these dyes are mentioned in Eng. Pats. 6875, 14,836, and 17,168 of 1890 (this Journal, 1891, 459, 830, and 831). The present invention describes the manufacture of isomers of azo-carmines which dye animal fibres red from an acid bath in shades different from that of azo-carmines. The process employed

is similar to that mentioned in Eng. Pat. 10,138 of 1892 (this Journal, 1893, 593) and more particularly referred to in Eng. Pat. 10,138n of 1892 (this Journal, 1893, 594). The methods there employed are the condensation of hydroxynaphthoquinone anil or its sulphonic acid with diamines and alkylated diamines. The new colouring matters described in the present specification are obtained by condensing sulphonated phenylene-*o*-diamines with hydroxynaphthoquinone anil or with its sulphonic acid. In the former case if phenyl-*o*-phenylene diamine sulphonic acid be employed, the product obtained can be converted into a soluble disulphonic acid by treatment with concentrated sulphuric acid, and the dyestuff so obtained is known as "iso-azo-carmines I." The colouring matter obtained by condensing phenyl-*o*-phenylene diamine sulphonic acid (*o*-amido-diphenylamine-*p*-sulphonic acid) with hydroxynaphthoquinone-anil-*p*-sulphonic acid is at once a disulphonic acid, and is known as "iso-azo-carmines II." Analogues and homologues of these substances may also be obtained by using, for instance, instead of the hydroxynaphthoquinone anil, the corresponding *o*- or *p*-toluides. In a similar manner the phenyl-*o*-phenylene diamine sulphonic acid may be replaced by the *o*- or *p*-tolyl-*o*-phenylene diamine sulphonic acid. The following proportions are given for preparing iso-azo-carmines I:—About 11 kilos. of *o*-amido-diphenylamine-*p*-sulphonic acid—

and 10 kilos. of  $\beta$ -hydroxynaphthoquinone anil are mixed with 200 kilos. of alcohol and 100 litres of water and boiled, when the new induline sulphonic acid separates out as a heavy precipitate. When a hot, faintly alkaline solution of the precipitate is completely precipitated by caustic soda and the mother-liquor is not coloured yellowish-red, the reaction is complete. The new phenyl-rosinduline sulphonic acid differs from its isomeride described in Eng. Pat. 15,259 of 1888 by giving alkaline salts soluble in hot and cold water. From the corresponding acids of Eng. Pat. 6875 of 1890 it can best be distinguished by its behaviour to sulphuric acid. About 10 kilos. of the phenyl-rosinduline sulphonic acid described above are stirred into 40 kilos. of concentrated sulphuric acid and heated to 100° C. until a test is soluble in 50 times its bulk of water. The melt is then poured on to 400 kilos. of ice and filter-pressed. After dissolving the press-cakes in boiling water an alkali is added and the dyestuff is precipitated by adding salt. Iso-azo-carmines I, thus obtained as an alkaline salt, is easily soluble in water, and dyes wool from an acid bath in bluer shades of red than the disulphonic acid of Eng. Pat. 15,259 of 1888. It differs from the disulphonic acids of Eng. Pat. 6875 of 1890, in that the colour of the solution of its sodium salt remains unchanged whether it is acid or alkaline. The new acid closely resembles or is practically identical with the sulphonic acid B of Eng. Pat. 17,168 of 1890. For the preparation of iso-azo-carmines II, about 10 kilos. of hydroxynaphthoquinone-anil sulphonic acid, and 8.5 kilos. of *o*-amido-diphenylamine-*p*-sulphonic acid are boiled with 100 litres of water. When the reaction is complete, caustic soda solution (containing about 35 per cent. NaOH) is added to the hot solution so long as a precipitate is produced. After cooling, the colouring matter is filtered off and purified by dissolving in water and reprecipitating with caustic soda. It very closely resembles in its properties iso-azo-carmines I, and the homologous colouring matters possess also very similar properties.—T. A. L.

*Improvements in the Manufacture or Production of Basic Compounds derived from Pyrazine.* H. E. Newton, London. From The Farbenfabriken vormals F. Bayer and Co., Elberfeld, Germany. Eng. Pat. 8824, May 2, 1893.

The inventors find that the distillates obtained by heating glycerol with any ammonium salt, contain only homologues of pyrazine mixed with water, ammonia, and substances possessing an aldehyde-like odour, 2,5-dimethylpyrazine being formed as the chief product, with only a small proportion of dimethylethylpyrazine. To prepare and

separate these two pyrazines the inventors acidulate the above distillate and distil with steam in order to separate the non-basic substances. The bases are removed by making alkaline and distilling, and solid caustic soda is then added to the distillate. The pyrazine bases are insoluble in the resulting concentrated alkaline solution and rise as an oily mass, from which the two bases are separated by distillation.

The 2,5-dimethylpyrazine boils at 155° C.

The second pyrazine obtained as above has the formula  $C_{11}H_8N_2$  and is 2:5-dimethyl-3-ethylpyrazine. It is a highly refractive liquid, boiling at 178–179° C.—J. G. W.

*The Manufacture or Production of Colouring Matters and Materials therefor.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer und Co.," Elberfeld, Germany. Eng. Pat. 8898, May 3, 1893.

THE first part of this specification refers to the preparation of substituted naphthalene derivatives by heating certain  $\alpha$ -naphthylamine sulphonic acids with a primary aromatic amine. In Eng. Pat. 7337A of 1892 (this Journal, 1893, 350) the method was described for obtaining alkylated naphthylamine sulphonic acids by heating certain naphthylamine sulphonic acids with aniline, *o*-, or *p*-toluidine with or without a salt thereof and in presence of benzoic acid. According to the present invention if the  $\alpha$ -naphthylamine sulphonic acid contains a sulphy group meta to the amido group, it also is replaced by the amine rest and a substituted *m*-naphthylendiamine results. For instance,  $\alpha$ -naphthylamine-*c*-disulphonic acid [1.3.1']  $C_{10}H_7NH_2(SO_3H)_2$  when heated with aniline and aniline hydrochloride is converted into diphenylnaphthylene diamine sulphonic acid [1.3.1']  $C_{10}H_7NHC_6H_5.NHC_6H_5.SO_3H$ . Similarly 1.3-naphthylamine sulphonic acid (Clève's  $\gamma$ -acid) when heated with *p*-toluidine and *p*-toluidine hydrochloride to 120–135° C. is converted into *p*-tolynaphthylamine sulphonic acid as described in Eng. Pat. 7337A of 1892, but if the temperature be raised to 140° C. sulphur dioxide is given off and 1.3-di-*p*-tolyl-naphthylene diamine is formed. By performing the operation in two stages and using different amines, mixed alkylated products can be obtained. All these products are to be employed for condensations with the nitroso derivatives of primary and secondary amines, forming rosinduline colouring matters and not isorosindulines as obtained according to Eng. Pat. 14,283 of 1886 and Eng. Pat. 3098 of 1890 (this Journal, 1891, 132). By condensing ditolyl-naphthylene diamine with nitro-*o*-dimethylaniline hydrochloride in an alcoholic solution a compound of the following constitution is obtained:—

This gives bluish-violet shades on cotton mordanted with tannic acid. On sulphonation with fuming sulphuric acid it yields a valuable sulphonic acid which dyes chromed wool a blue or greenish-blue shade, fast to soap and washing. Sulphonic acids of these dyestuffs can also be obtained by using sulphonic acids as original components for condensation, as, for example, a blue for wool is produced by condensing 1.3-di-*p*-tolyl-naphthylene diamine-1'-sulphonic acid with nitroso-ethyl-benzylaniline sulphonic acid in an alcoholic solution in presence of sodium acetate. The dyestuff obtained stands fulling and alkalis.—T. A. L.

*The Production of New Colouring Matters for Dyeing and Printing* Read Holliday and Sons, Ltd., and L. Holliday, Huddersfield. Eng. Pat. 9689, May 15, 1893.

By heating rosaniline with  $\beta$ -naphthylamine, Meldola (Chem. News, 1883, 1, 133) obtained some naphthylated rosanilines which on sulphonation dyed wool and silk redder shades of blue than the corresponding sulphonic acid of

triphenylrosaniline. By varying the conditions of the melt it is possible to obtain grimmer shades than from the phenylated rosanilines, and the proportions given are as follows:—100 lb. of rosaniline, 500 lb. of  $\beta$ -naphthylamine, and 5 lb. of benzene or glacial acetic acid are heated to 160° C. until a sample dissolved in alcohol and acetic acid, and spotted on paper, appears greenish blue by gas light. The time required is about 5 hours, when the melt is cooled and the excess of  $\beta$ -naphthylamine removed by hot hydrochloric acid and water. In order to sulphonate it, 100 lb. of the crude product are stirred into 300 lb. of sulphuric acid of 60° B. without the application of external heat until a sample washed with cold water dissolves in dilute ammonia. The melt is then poured into water, washed, and dried down with a slight excess of ammonia. By stopping the sulphonation at an earlier or carrying it on to a later stage other products can be obtained which can also be used in dyeing and printing.—T. A. L.

*The Manufacture or Production of Azo Colouring Matters.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer und Co.," Elberfeld, Germany. Eng. Pat. 9894, May 17, 1893.

THE colouring matters described are obtained by reacting with two molecular proportions of the same or of different diazo compounds on one molecular proportion of 1:1'-amido-naphthol 4-sulphonic acid obtained by the action of alkalis on  $\alpha$ -naphthylamine disulphonic acid 8. The products obtained dye blue to bluish-black shades, and are said to be fast to light.—T. A. L.

*Manufacture of Basic Colouring Matters.* C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin. Eng. Pat. 9069, May 18, 1893.

VIOLET-BLUE to blue colouring matters are produced by oxidising the unsymmetrically mono- or di-alkylated *p*-phenylene diamines or their salts, together with diphenyl-*m*-phenylene diamine or its homologues. The alcoholic solution of dimethyl-*p*-phenylene diamine hydrochloride obtained from 2.5 kilos. of nitrosodimethylaniline hydrochloride is mixed with 2.9 kilos. of di-*p*-tolyl-*m*-phenylene diamine. After heating to about 70° C. a strong solution of 3.75 kilos. of sodium bichromate is added. The mixture is boiled for 1 hour, and 100 litres of water and 30 litres of brine are then added, when the colouring matter precipitates on cooling. In order to purify it, it is dissolved in boiling water, filtered from the oxide of chromium, and precipitated with salt.—T. A. L.

*The Manufacture or Production of Colouring Matters and Processes for Dyeing and Printing therewith.* H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer und Co.," Elberfeld, Germany. Eng. Pat. 9,972, May 18, 1893.

THE specification refers to the production of mixed tetrazo-dyestuffs by combining one molecular proportion of tetrazo-diphenyl or one of its analogues with one molecular proportion of a naphthylamine sulphonic acid, naphthol sulphonic acid, amidonaphthol sulphonic acid, or di-hydroxy-naphthalene sulphonic acid, and subsequently with one molecular proportion of aniline, *o*-toluidine, *p*-xylylene, *o*- or *m*-amido-phenol ether, *o*- or *m*-amido-*p*-cresol ether, or the order of these operations may be reversed. The colouring matters dye unmordanted cotton red to reddish violet and violet, are capable of being diazotised on the fibre, and on development give shades varying from reddish-violet and violet to blue, fast to washing.—T. A. L.

*Improvements in Inks.* E. Nicolson, and L. Goldmark, New York, U.S.A. Eng. Pat. 3276, February 11, 1894.

ANY ordinary writing ink is evaporated down in the presence of a suitable non-porous material, such as granulated quartz,

so that the particles are about  $\frac{1}{30}$  inch in diameter. In this way the granules become coated with a firmly-adhering layer of dried ink, and may be handled and shipped, &c., as a dry powder. For use, they are placed in a bottle and just covered with water, the ink being at once dissolved. The patentees claim that they leave no sticky residues in the bottles, and that the granules serve to keep the nibs always clear and sharp.—F. H. L.

## V.—TEXTILES: COTTON, WOOL, SILK, Etc.

*Fire-proofing Compounds.* P. Lochtin. Dingler's Polyt. J. 290, 230—235.

THE systematic testing of about 50 different substances for their capacity of rendering materials unflammable, showed that the compounds recommended for this purpose are of very unequal value. Thus, by holding in the flame of a candle, strips of filtering paper uniformly impregnated with solutions of the various bodies containing 20, 15, 10, 5, 3·5, 2, 1, and 0·5 per cent. of anhydrous substance, or charged with an insoluble body precipitated from such solutions, it was found that, while some were rendered practically unflammable, others did not appear to be much affected by the impregnation, or had become even more combustible than pure paper. In accordance with the results of a great number of such experiments, the substances employed are classified as follows:—

1. *Substances increasing Combustibility.*—Sodium sulphate, sodium sulphite, sodium thiosulphate, sodium silicate, sodium carbonate, sodium stannate, sodium tungstate, sodium chloride, potassium sulphate, potassium phosphate, potassium chloride, zinc carbonate, calcium carbonate, magnesium carbonate, calcium sulphate, ferrous sulphate, magnesium hydroxide.

2. *Indifferent Substances or Bodies, which are effective only when used in large quantities.*—Magnesium sulphate, aluminium borate, zinc borate, calcium phosphate, magnesium phosphate, aluminium phosphate, zinc phosphate, sodium acetate, potassium acetate, silicic acid, sodium phosphate, aluminium hydroxide precipitated from an acid solution, tungstic acid, ammonium tungstate, potassium carbonate.

3. *Substances which render Cellulose specifically unflammable.*—Ammonium sulphate, ammonium phosphate, ammonium chloride, calcium chloride, magnesium chloride, zinc chloride, zinc sulphate, stannous chloride, alum, borax, boric acid, aluminium hydroxide precipitated from sodium aluminate.

The lowest strengths of solution and the least quantity of substance (anhydrous) necessary for rendering 100 parts of cellulose unflammable are given in the following table. The figures to be taken as approximate only:—

Name of Substance.	Lowest Percentage of Substance in Solution necessary to render Cellulose Unflammable.	Least Quantity of Substance required for rendering Unflammable 100 parts of Cellulose.
Ammonium chloride.....	1·5	1·2
„ phosphate ..	1·5	1·5
„ sulphate ....	1·5	4·5
Zinc chloride.....	1·5	1·0
Calcium chloride .....	1·5	1·5
Magnesium chloride.....	1·5	1·5
Aluminium hydroxide ...	1·5	3·8
Alum.....	2·0	..

Name of Substance.	Lowest Percentage of Substance in Solution necessary to render Cellulose Unflammable.	Least Quantity of Substance required for rendering Unflammable 100 parts of Cellulose.
Zinc sulphate.....	1·5	4·5
Stannous chloride .....	2·5	..
Borax .....	1·5	8·5
Boric acid .....	2·5	10·0
Potassium carbonate.....	7·5	..
Magnesium sulphate.....	7·5	15·0
Sodium chloride .....	15·0	35·0
„ silicate.....	17·5	50·0
Silicic acid.....	12·5	30·0
Potassium chloride .....	20·0	45·0

„ phosphate .....	Above 15	..
Tungstic acid.....	„ 10	Above 15
Sodium tungstate.....	„ 10	„ 15
Ammonium „ .....	7·5	„ 10
Clay (air-dried).....	..	75·0
Sodium and potassium acetates.	7·5—5·0	..

Of these substances the three first-mentioned ammonium salts and aluminium hydroxide may be considered to be the best adapted for practical purposes. The explanation of the fire-proofing properties of the ammonium salts is to be found in their becoming volatilised and dissociated by the influence of heat, the vapours formed producing an uncombustible mixture with the combustible gases. Calcium, magnesium, and zinc chlorides act in a similar manner through the separation of hydrochloric acid. Sodium and potassium chlorides being unalterable by heat are also ineffective as fire-proofing materials. Zinc sulphate and alum likewise owe their effectiveness to dissociation by heat. The action of aluminium hydroxide is a purely mechanical one, hence the striking difference in the behaviour of the granular modification left after drying of the voluminous precipitate from an aluminium salt and that of the exceedingly finely-divided product obtained by the action of carbonic acid upon a solution of sodium aluminate.

As regards the increased combustibility of paper after impregnation with the substances enumerated above, this appears likewise to be owing to a mechanical action, resulting in the prevention of loss of heat.

For practical use the following strengths of solutions are recommended:—

10 to 15 per cent. for textile fabrics, stage decorations, &c.

20 to 30 per cent. for pasteboard, thin boards, &c.

25 to 30 per cent., applied twice or three times, for heavy timber, thick boards, &c.

As an addition to the water used for extinguishing fires, calcium or magnesium chlorides might be useful.—F. M.

*English Jute-Fibre.* A. Pears, jun. Proc. Chem. Soc. 1894 [137], 85-89.

In continuation of previous observations (this Journal, 1893, 599), the seed saved from the plants grown in 1892 was sown at two periods, March and June 1893. Parallel with these, cultivations were made from Indian seed. The plants were cut down in the late autumn when the seed is mature, and the four specimens of fibre obtained were compared.

Slight differences were observed in the resistance to hydrolysis and in the percentages of cellulose, the specimens from the early sowings being the better.

It is evident from the study of these artificial cultivations, that they exhibit the essential features of jute-fibre, and differ chiefly in the degree of hydration, which is dependent on the conditions of growth. The specimen may, in fact, be regarded as a hydrated modification of the normal fibre, with which it corresponds in all the characteristic properties, differing merely in external features (colour, softness, &c.).

## VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

### PATENTS.

*An Improved Process of Dyeing for producing Genuine Turkey Red and Rose Colour in Yarn Hanks and Fabrics.* W. P. Thompson, Liverpool, Manchester, and London. From E. Haeffely, Barmen, Germany. Eng. Pat. 3378, February 16, 1891.

This patent is identical with Eng. Pat. 23,559 of 1893 (this Journal, 1894, 391), for which the patentees are E. Hölken and Co., Barmen.—R. B. B.

*Improvements in Printing on Cotton Fabrics.* E. Iantsch, Hilden, Prussia. Eng. Pat. 3550, February 19, 1894.

The fabric is dyed with a direct cotton colour and then padded with  $\beta$ -naphthol. A reducing discharge is printed on the cotton; this may consist of zinc dust or a stannous salt. After steaming, the fabric is printed with a diazo body, such as benzidine, which produces an insoluble coloring matter on those portions not covered by the resist. The goods are finally steamed, washed, and soaped.—R. B. B.

*Improvements in the Method of and Apparatus for Dyeing, Mordanting, and otherwise treating Woven or Felted Fabrics and Yarns.* J. Relfitt, Leeds. Eng. Pat. 9682, May 15, 1893.

The process described in this patent consists, in its simplest form, of four operations: (1) the fabric is passed through water and between rollers to ensure equal wetting throughout; (2) it is caused to travel in contact with a perforated roller which revolves in a vessel partially filled with dye-liquor, the fabric thus absorbing the dye-liquor from the roller; (3) it then enters a steam-box, and, passing therein in a zig-zag manner over a number of rollers, is subjected to the action of steam; after which it (4) passes between a pair of rollers revolving in water, whereby it is cooled and partially washed. It will often be found advantageous to work with three such machines connected together.

When dyeing thick or heavy goods, in order to ensure that the dye-liquor penetrates the fabric, it is necessary to

dye both sides of the fabric, and when this is the case two dye-vessels and dye rollers are provided in each machine.

The special advantages claimed for the apparatus are, (1) thorough and even dyeing, and (2) the small quantity of dye liquor required. The bulk of the waste liquors is greatly reduced, and the pollution of rivers, &c., minimised.

R. B. B.

*Improvements in or connected with Dyeing, Finishing, Sizing, and Bleaching, or similarly operating upon Textile Fabrics or Fibres and other Materials.* J. Smith Heywood. Eng. Pat. 10,327, May 25, 1893.

The improvement consists in the use of a vessel of U shape or semi-annular form. The warps, pieces, &c., are fastened together and passed in at one end of this vessel, through which they are carried by mechanical means, such as travelling brattice conveyors. The goods may be successively passed through two or more such vessels to undergo bleaching, mordanting, or dyeing operations.

The advantages claimed are (1) the amount of liquor required is small, (2) only a small space is taken up by the apparatus.—R. B. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*The Motion of Gases in Ducts and Towers.* K. W. Jurisch. Chem. Ind. 16, 425-435.

WHEN a gas passes through a tube, the velocity of motion at the axis is necessarily greater than that at the periphery, since delay is caused by friction against the sides of the pipe. It is usual to assume that the mean velocity in a round tube is the same as that at a spot situated at a distance from the side equal to one-third of the radius. The author has made a variety of measurements showing that this assumption is only approximately correct, the limits of error found lying between - 5 and + 30 per cent.; so that when a greater degree of accuracy is requisite, the velocities at various distances from the side must be measured, and the average value deduced therefrom. Thus, in the case of the gases passing to a Gay-Lussac tower through a circular leaden tube of 10.76 inches radius, the velocities at different distances from the side (observed by means of a Fletcher's anemometer) were as follows:—

Distance from Side,	Anemometer Reading,	Velocity in Feet per Second.
Inches.	Inch.	
1	0.020	4.968
2	0.025	4.514
3	0.030	4.195
4	0.035	5.731
5	0.040	5.716
7	0.045	6.556
8	0.045	6.556

From these values the velocity in each concentric annulus of cross section is calculated, the mean of the whole being 4.968 feet per second; whereas the velocity at one-third of the radius is 5.116 feet per second, or 103.25 per cent. of the true value.

In similar fashion, the exit gases from a hydrochloric acid condensing tower gave the following figures, the

diameter of the tube being 15 inches (Jones' saltake roasters employed):—

Distance from Sale.	Anemometer Reading.	Velocity in Feet per Second.
Inches.	Inch.	
0.5	0.005	8.500
1.5	0.115	9.682
2.5	0.115	9.682
3.5	0.140	10.650
4.5	0.155	11.235
5.5	0.160	11.420
6.5	0.165	11.600
7.5	0.175	11.945

These values lead to the figure 9.953 feet per second as the actual average velocity, whilst the velocity at one-third the radius is 9.682 feet per second, or 97.28 per cent. of the true value. A similar series of observations a month later gave 8.235 as true average velocity, and 8.075 as that at one-third the radius, = 98.05 per cent. of the true value. A third series made at a different period of working off the charges gave 6.321 as the true velocity and 6.384 as that at one-third the radius, = 101 per cent. Several other similar series of observations gave values at one-third the radius varying between 96.92 and 132.23 per cent. of the true average velocity.

Analogous results were obtained in the case of much wider tunnels conveying hot air and gases from saltake furnaces to the condensers; thus, with a tunnel of 52.5 inches radius, the following figures were obtained:—

Distance from Sale.	Anemometer Reading.	Velocity in Feet per Second.
Inches.	Inch.	
1	0.005	2.019
3	0.010	2.855
5	0.015	3.497
8	0.035	5.342
12	0.035	5.342
14	0.035	5.342
16	0.040	5.719
20	0.050	6.384
24	0.035	5.342
30	0.045	6.056
36	0.045	6.056
42	0.050	6.384

Whence the true average velocity is deduced as 3.434 feet per second, that at one-third the radius being 4.0 feet per second, = 116.5 per cent. In a second series of observations 1.206 was the true average velocity deduced, and 5.41 that at one-third the radius, = 128.62 per cent.—C. R. A. W.

*The Densities of Solutions of Soda and Potash.* S. U. Pickering. Phil. Mag. 37, 359—375.

Solutions of soda and potash were prepared from sodium and by crystallisation from alcohol respectively: the lumps were first washed in well-boiled water to remove any adhering carbonate, and were then dissolved to form nearly saturated solutions, which were filtered through glass-wool. The strength of the stock solutions was determined by titration, weaker fluids being prepared by addition of

known weights of water. The temperature throughout was  $15 \pm 0.01$ . Several different series of observations were made for the purpose of more completely eliminating errors; on plotting the results with densities and percentage compositions as variables the curves obtained show that throughout, the density increases with the strength at a decreasing rate with soda and at an increasing rate with potash. The following tables are ultimately deduced:—

#### DENSITY OF SODIUM HYDROXIDE SOLUTIONS AT 15° C.

Percentage of NaOH.	Density.	Percentage of NaOH.	Density.
0	0.999180	26	1.287390
1	1.010611	27	1.298877
2	1.021920	28	1.309708

36	1.35485	52	1.53822
37	1.36586		

The original plottings do not exhibit perfectly continuous curves, breaks being visible at various places; in the case of the soda curve these correspond with the following definite hydrates:—

Breaks in Density.	Hydrates Isolated and Breaks in Freezing Point Figure.
42.6 per cent. NaOH	42.55 per cent. NaOH = NaOH, 3H <sub>2</sub> O
38.77 " "	38.83 " " = NaOH, 3.5H <sub>2</sub> O
35.0 " "	35.71 " " = NaOH, 4H <sub>2</sub> O
29.4 " "	30.77 " " = NaOH, 5H <sub>2</sub> O
24.05 " "	24.10 " " = NaOH, 7H <sub>2</sub> O
20.0 " "	19.89 " " = NaOH, 9H <sub>2</sub> O
12.1 " "	13.3 " " = NaOH, 16H <sub>2</sub> O
5.4 " "	4.0 " " = NaOH, 33H <sub>2</sub> O

Six of these hydrates have been previously isolated in the crystalline condition, whilst in all cases the breaks indicated by the freezing method agree closely with those shown by the density method.

In the case of the potash curve the breaks indicated are less sharply marked; four are noticeable, situated respectively at—

43.2 per cent.	= KOH, 4.65 H <sub>2</sub> O
35.4 " "	= KOH, 5.68 H <sub>2</sub> O
19.0 " "	= KOH, 13 H <sub>2</sub> O
8.0 " "	= KOH, 36 H <sub>2</sub> O

**Preparation of Ammonium Nitrate from Sodium Nitrate and Ammonium Sulphate.** Fr. Benker, Clichy. Ger. Pat. 69,148, November 20, 1891. Chem. Ind. 16, 437.

On mixing solutions of sodium nitrate and ammonium sulphate and refrigerating, most of the sodium sulphate formed separates out; the remainder is treated with nitric acid, whereby sodium nitrate and sulphuric acid are formed, so that by repeated coolings ammonium nitrate separates. The mother-liquors are neutralised with soda and used over again to dissolve sodium nitrate and ammonium sulphate.

—C. R. A. W.

*The Action of Salts on Acids.* R. W. Wood. Amer. Chem. J. 15, 663—670.

DUGGAN has pointed out the value of diastase and starch as an indicator of neutrality, since the presence of a small trace of acid or alkali prevents the action of the ferment (Amer. Chem. J. 8, No. 3). In the case of weak acids, however, a small amount of their neutral sodium salts prevents this, and in consequence Duggan concludes that these salts are alkaline. The author regards the prevention of the inhibitory action of weak acids, in the manner described, as due to other causes depending upon the dissociation of the salts, and considers that the preventive action upon diastase is due to free hydrogen ions in the case of acids, and to free hydroxyl ions in that of alkalis. The preliminary experiments in support of this idea include the action of caustic soda and of several of the fatty acids and their salts upon the fermentation of malt by diastase. One part of sodium hydrate in 1,000,000 of starch paste has a sensible effect on the quantity of maltose formed in a given time; hence the test is most sensitive, for 5 parts to 1,000,000 of water are necessary for phenolphthalein to give a coloration. The effect of acids is less than that of alkalis, and in all cases a slight amount of acid helps the fermentation, a fact attributed to the presence of a small quantity of impurity of an alkaline nature in the starch. The action beyond this point is to prevent the fermentation, and its extent depends on the nature of and quantity of the acid and upon the temperature, the preventive power of the acid increasing with the temperature to a much greater extent than the power of the diastase. For instance, although diastase is most active at 55° C., yet in the presence of acid 45° C. is a far more favourable temperature. Neutral salts of the weaker acids have a slight retarding effect, and as a rule, the weaker the acid the greater is the retarding action. Salts of strong acids, such as sodium chloride, have little or no effect. The action of weak acids in presence of their neutral salts is to first increase the formation of maltose, owing to their neutralising action upon the impurity in the starch, and beyond this point it is necessary to add several equivalents of the acid (two in the case of acetic acid) before any retardation occurs.—C. A. K.

*Formation of Phosphorus from the Phosphates of the Alkalis and Alkaline Earths by Means of Aluminium as Reducing Agent; and the Action of Aluminium upon Sulphates and Chlorides.* A. Rossel and L. Frank. Ber. 27, 52—55.

When microcosmic salt,  $\text{NH}_4\text{NaHPO}_4$ , is fused in a porcelain crucible until sodium metaphosphate,  $\text{NaPO}_3$ , is formed and small pieces of aluminium foil are then thrown into the fused salt, little flames are at once observable. If the operation be conducted in a glass tube in an atmosphere of dry hydrogen, phosphorus distils over. The formation of the phosphorus takes place slowly, but is much accelerated when the aluminium is used in the form of powder. The reaction is complex, and a residue is obtained that contains aluminium oxide, sodium aluminate, and a phosphorus-aluminium compound, which is stable at a high temperature, but which is decomposed by water into aluminium oxide, phosphoric acid, and phosphoretted hydrogen. Metaphosphoric acid and phosphorus pentoxide are also reduced at a red heat by aluminium.

The nature of the phosphorus-aluminium compound was investigated by leading phosphorus vapour, heated to a high temperature, over aluminium at a high temperature, and the product obtained was strongly heated until it ceased to evolve phosphorus. The compound formed was then found to be a grey crystalline powder, of uniform composition, which is expressed by the formula  $\text{Al}_2\text{P}_3$ . From the properties of this body, the authors conclude that it may be assumed that this substance is formed on the reduction of the phosphates by aluminium, although they are not able, with certainty, to deduce an equation. They

showed by quantitative determinations that from 28 to 31 per cent. of the phosphorus of the sodium metaphosphate distilled over.

Experiments were next made with the phosphates of calcium and magnesium, and it was found that at a high temperature all phosphates of these metals were decomposed by aluminium. When bone-meal, ground mineral phosphate, powder from fossil bones, magnesium pyrophosphate, calcium metaphosphate, are heated to redness with aluminium, more or less phosphorus distils, and a residue is obtained that behaves like the residue resulting from the reaction upon sodium metaphosphate.

It was further found that these residues, and also the phosphor-aluminium, were acted upon when heated with silica, a fresh liberation of phosphorus taking place. Calcium metaphosphate (or sodium metaphosphate) were then mixed with aluminium and silica in the proportions corresponding to the equations—

or

and heated to redness. The phosphorus, under these conditions, formed in a continuous steady manner, and was so completely expelled from the mixture that the residue scarcely retained a trace of it.

On repeating this experiment and using "superphosphate" (calcined bones were treated with two molecules of sulphuric acid, the mixture heated to redness, and afterwards ground) the reaction was so intense that a not inconsiderable explosion resulted. This unexpected result led to the trial of the action of aluminium upon sulphates.

When barium sulphate was heated with aluminium powder, an intense reaction set in, accompanied by a powerful explosion and by liberation of sulphur. The same reaction occurred with gypsum or calcium sulphate, which explains the intense reaction that took place when the mixture of aluminium, silica, and superphosphate was heated.

It was also found that chlorides were decomposed by aluminium, even sodium chloride, and some of them (chromium chloride) with liberation of chlorine. These reactions the authors will describe later; but they now make use of hydrochloric acid instead of sulphuric acid for converting the orthophosphates into metaphosphates, in which case the phosphorus is yielded by them without explosion, on heating with a mixture of aluminium and silica.—H. S. P.

#### *Decomposition of Sodium Peroxide by Aluminium.*

A. Rosel and L. Frank. Ber. 27, 55.

Sodium peroxide ( $\text{Na}_2\text{O}_2$ ) is for many purposes an admirable oxidising agent, which, however, must be used carefully, as Victor Meyer has already shown.

The authors use it in aqueous solution to oxidise the residues they have obtained when making phosphorus by the action of aluminium upon the phosphates (see preceding abstract). It acts on these residues vigorously, but not dangerously.

The reaction is quite different when aluminium powder and sodium peroxide are mixed together. When this mixture is exposed to the air for a short time the moisture that is absorbed by the sodium peroxide suffices to set up a spontaneous combustion. This may likewise be induced at once by the addition of a few drops of water, and is accompanied by the production of a very high temperature. This mixture must therefore be regarded as highly dangerous, and should be used with caution.—H. S. P.

#### *The Manufacture of Aluminium Sulphate.* K. Jurisch. Chem. Ind. 17, 89—93.

In the manufacture of sulphate of alumina the aim at present is to produce an article as free as possible from iron and containing 14—14.5 per cent.  $\text{Al}_2\text{O}_3$ , free from an excess of acid or of alumina, and thus yielding a clear aqueous solution.

In the usual way of treating bauxite with soda ash it is advantageous to decompose the red variety of bauxite, containing 2 per cent. of silica and yielding a ferric oxide almost wholly insoluble in the lye. The bauxite is calcined, ground, mixed with ash in the proportion of 1 of sesquioxide to 1.2 of soda ash, and subjected to a white heat (but not to fusion), say in Thomson's cryolite furnace. The melt should contain three-fourths of the total alumina in the soluble form. The lixiviation of the mass is best performed by means of weak caustic alkali (say 0.5 equivalent), since otherwise the lye readily deposits aluminium hydrate on contact with the insoluble residue. In any case the lixiviation should be effected with expedition, and hence the melt is ground up, introduced into the boiling solution, and after 5—10 minutes agitation is drawn off as a solution marking no less than 64° Tw. and containing 1 mol. of  $\text{Al}_2\text{O}_3$  to 1.8—2 mols.  $\text{Na}_2\text{O}$ , or 170—175 grms.  $\text{Al}_2\text{O}_3$  per litre. The filter-pressed solution is allowed to settle again and carbonated at 50°—90° C., when alumina is precipitated in a granular form and almost free from silica and iron. The filtered solution is available for the manufacture of soda crystals, whilst the slightly washed precipitate is introduced into sulphuric acid of 160° Tw., which is introduced into a steam-jacketed copper vessel and heated to 100° C. When all effervescence ceases the solution is run off into lead-lined crystallisers and allowed to cool, with occasional agitation. The colour when yellowish may be masked by the addition of copper sulphate to the hot solution. About 75 per cent. of the iron contained in the final product is introduced with the sulphuric acid. Aluminium sulphate thus manufactured has the following average composition:—

$\text{Al}_2\text{O}_3$ , 14.5;  $\text{SO}_3$ , 33.7;  $\text{Na}_2\text{SO}_4$ , 0.6;  $\text{Fe}_2\text{O}_3$ , 0.02; insoluble, 0.50; water, 50.68 per cent.—H. A.

#### *Fire-proofing Compounds.* P. Loebtin. Diagler's polyt. J. 290, 230.

See under V., page 512.

#### *The Action of Light on Oxalic Acid.* A. Richardson. Proc. Chem. Soc. 1894 [137], 88.

Downes and Blunt, in 1879, observed that solutions of oxalic acid evolve carbon dioxide when exposed to light. In the present paper the author shows that hydrogen peroxide is also formed. Experiments are described in which this was found to be the case with numerous specimens of oxalic acid obtained from different sources, and carefully purified. The presence of the peroxide was proved by the titanous acid and chromic acid tests.

The results of experiments in which the carbon dioxide evolved during the decomposition of a known weight of acid was estimated, showed that the oxidation of the carbon was complete.

Whilst the total amount of hydrogen peroxide formed in the solution increased with the concentration of the acid, the proportion of peroxide formed to acid decomposed, simultaneously decreased. The author draws the following conclusions:—

- (1) Hydrogen peroxide is stable in solutions of oxalic acid in the dark.
- (2) It is fairly stable in these solutions when exposed to light if excess of oxygen be present.
- (3) Rapid decomposition of hydrogen peroxide occurs in solution of oxalic acid in absence of oxygen when their solutions are exposed to light.

## PATENTS.

*Improvements in and Apparatus for obtaining Cyanogen, Cyanides, and other Products from Carbonaceous Matter or Substances containing Ammonia or Compounds thereof.* H. Aitken, Darroch, N.B. Eng. Pat. 4037, February 23, 1893.

The invention partly relates to utilising the gases produced in blast-furnaces for smelting iron and other ores, or oil- or gas-producers of the blast-furnace or Siemens type; and partly to a furnace specially devised for the production of cyanogen compounds. The latter apparatus consists, as shown in the drawing, of two producers connected by the flue Y, in all respects similar, which are charged through the bells P, provided with valves p, with carbonaceous matter, and lime or alkalis, into the chambers A;

k is a tap-hole for running out any molten metal when an ore is used with the charge. B are the slag-holes, C the tuyères, and E an aperture into the furnace from the chambers e, in which chambers may be placed an alkali. When both producers are fired the hot blast is supplied to No. 1, the dampers i i being closed, and the resulting gases pass through the conduit Y and have exit by E e in No. 2 into a dust chamber, whence they pass into a scrubber, containing, for instance, solution of an iron salt, and provided with suitable appliances for ensuring contact of the gases with the liquid. When the temperature in No. 2 falls too low, the current is reversed, the blast enters No. 2, and the gases have exit through No. 1, and thus the functions of the two producers are alternated indefinitely.

A single chamber may be used by taking off the gases at the top when combustion is well established, and then forcing in air at the top, with or without steam, and drawing off the products at or near the bottom. When it is desired to make an ordinary producer-gas, with cyanogen or its compounds, the tuyères are placed on one end of the furnace, and part of the gases pass off at the top in the usual manner, while the remainder are drawn off near the bottom, as shown in the duplex apparatus. Holes are provided in the chamber through which potash or other alkali, or nitrogenous substances, such as horns, hoofs, or the like, are introduced. Or gases rich in nitrogen, as ammoniacal gases, may be passed in regulated quantities into the furnace through these holes, for conversion into cyanogen compounds.

When the invention is applied to iron blast-furnaces, a valved pipe inclined upwards outwardly, and connected at its outer end by a vertical pipe to the dust-collecting and scrubbing apparatus, is inserted, preferably just above the level to which the slag is allowed to rise, so as to avoid any unnecessary mixture of free oxygen with the gases. Extra carbonaceous matter and lime may be added in the furnace, so as not to affect the quality of the iron made. In taking off gas from gas-producers of the Siemens type, the gases taken off are drawn as far as possible directly from the hot carbonaceous matter. In all cases the gases withdrawn may, after deprivation of cyanogen compounds, be returned

to the furnace or otherwise utilised. It is considered that atmospheric nitrogen takes part in the formation of cyanogen under the conditions described.

The dust collected in the dust chambers from the gases drawn off is washed for the cyanides it may contain. The salts used in the scrubber may be the sulphate, chloride, oxide, carbonate, or sulphide of iron, and these after use may be treated with sodium or potassium salts to obtain the corresponding ferrocyanide, which may be treated in any desired way to produce marketable cyanogen salts.

—E. S.

*Improvements in the Production of Alkali and in Apparatus therefor, the said Apparatus being applicable for Electrolysis generally.* J. Haigreaves, Farnworth-in-Wilms, and T. Bird, Cressington, Liverpool. Eng. Pat. 5197, March 10, 1893.

See under XI., page 528.

*Improvements in the Manufacture of Manganese Peroxide.* G. S. Albright, Oldbury, Worcester, and J. J. Hood, Shepherd's Bush Road, Middlesex. Eng. Pat. 9271, May 9, 1893.

Manganous sulphate is prepared, as a preliminary to obtaining manganic hydroxide, or a mixture of the peroxide with the monoxide and calcium oxide, known as Weldon mud, for application to such purposes as gas purification, &c. Manganese ores containing the peroxide are mixed with coal dust and sulphuric acid, and the mixture is heated on a furnace bed. Manganous sulphate is washed out of the product. Ores not containing the peroxide are simply heated with sulphuric acid until any iron present is rendered insoluble. Spent manganous oxide from gas-works may be roasted to obtain sulphuric acid and a residue of manganous sulphate; or it is simply heated with sulphuric acid, with or without hydrochloric acid, to obtain a residue of manganous sulphate and chloride, with calcium sulphate and free sulphur, which is lixiviated, and sulphur is distilled off the insoluble portion.

The manganous sulphate solution is treated with calcium chloride in excess; the calcium sulphate that forms is separated, and the washings are made with strong calcium chloride solution, the presence of which in the subsequent oxidation process is necessary. The manganous sulphate solution with calcium chloride and lime is then treated with air in a Weldon oxidiser to obtain the "mud." The calcium chloride remaining in solution is employed again for preparation, as before, of manganous chloride from the sulphate.

According to another process, the manganous sulphate solution is precipitated by ammonia, and air is blown in to precipitate the manganese as Weldon mud. The ammonia blown out is recovered, and the ammonium sulphate formed in the solution is drawn off and evaporated.

Weldon mud may be purified by treatment with dilute cold hydrochloric acid. Similar processes may be applied to recover manganic oxide from spent "mud" used in gas purification.—E. S.

*Improvements in Separating Salts of Soda and Potash, and particularly Common Salt, from Solutions of Magnesium Chloride.* T. H. Bell, Middlesbrough. From T. Schloosing, Paris. Eng. Pat. 10,341, May 25, 1893.

The inventor refers to a former patent, No. 11,469, 1891 (this Journal, 1892, 686), in which "chloride of magnesium in grains" is obtained by concentration of a solution, associated with sodium or potassium salts, which form small crystals and fall as the evaporation proceeds. He now finds that sodium chloride dissolved in magnesium chloride solution, is much more soluble hot than cold, so that much of the sodium salt may be obtained in large crystals by simply cooling the solution previously suitably concentrated. The solution of magnesium chloride obtained after having distilled upon magnesia the mother-liquor resulting from the manufacture of sodium carbonate by the

ammonia process, contains a large proportion of sodium chloride. These liquors, cleared from excess of magnesia, are concentrated until salting-out commences, and are then allowed to cool, or are cooled by an outer flow of cold water, when about half the sodium salt present separates in large crystals. The solution is run off these crystals, and the concentration and cooling are repeated; the solution is then again concentrated, and the fine crystals which form are fished out. These fine crystals are mixed with the larger crystals previously obtained, and are washed and dried.

In dealing with the magnesium chloride recovered in the process for obtaining chlorine from that salt, the solution being dilute and free from sodium salts, may be strongly concentrated in a boiler without danger of forming a deposit. Such a strong solution may then be added to the magnesium chloride solution containing common salt, obtained in the soda-ammonia process mentioned in the preceding paragraph, and the proportion of magnesium chloride present being thus greatly increased, a single concentration suffices to obtain about three-fourths of the whole sodium chloride in large crystals. After further concentration of the cleared solution, the remainder of the sodium chloride is salted out.—E. S.

*Improvements in connection with Electrolytic Apparatus.*  
H. Y. Castner, London. Eng. Pat. 10,584, May 30, 1893.

See under XI., page 529.

*Improvements in Calcining Apparatus for the Conversion of Bicarbonate of Soda into Carbonate of Soda and other Uses.* La Société Marcheville Daguin and Company, Paris. (Under Internat. Convention, date claimed December 3, 1892.) Eng. Pat. 12,997, July 3, 1893.

A CIRCULAR revolving hearth is supported by a set of conical rollers, and carries a vertical cylinder, perforated in places for outflow of gases, issuing into it from a series of superposed retort sections, which it traverses. The retort sections are so formed, with alternately inclined upper and lower sides, that the salt (such as sodium bicarbonate) fed into the upper part of the cylinder and directed outwards by a conical diaphragm, is carried first to the periphery, and then towards the centre of the section before it falls into the next section, an annular space being left for the purpose about the cylinder, which latter carries, so as to revolve with it, conical discs extending into each retort section. The upper internal face of each retort chamber has one or more scrapers, as has also each conical disc. In the example given, the retort sections are caused to revolve independently of, and in a contrary direction to, the central cylinder, the mechanism for effecting which is shown. The material or salt treated falls from the lowest retort section on to the hearth, over which is an arched space, channelled to admit heating gases. Adjustable rakes are provided for the hearth. The series of retorts is enclosed in a fixed casing of refractory material supported upon pillars, and supporting the fixed arch over the hearth. The casing is pierced on opposite sides of the space occupied by the retorts; on one side, to admit heating gases, and on the opposite side for discharging the products of combustion. The use of conical track rollers constitutes a claimed feature in the apparatus.—E. S.

## VIII.—GLASS, POTTERY, AND ENAMELS.

*The Preparation of Anhydrous Crystalline Silicates.*  
H. Traube. Ber. 26, 2735.

On adding a solution of zinc sulphate to one of sodium silicate an amorphous precipitate of zinc silicate is obtained.

The zinc silicate will be contaminated with zinc hydroxide in the event of the sodium silicate containing free alkali. Zinc silicate prepared in this manner as nearly free from zinc hydroxide as possible, was dried and exposed, together with eight times its weight of fused boric anhydride, in a platinum crucible to the highest temperature of a porcelain furnace in the Royal Porcelain Works of Charlottenburg, for a period of 10 days. At the end of this period the bulk of the boric anhydride had volatilised, and on dissolving the remainder in water a white crystalline product insoluble in acids was obtained. This body was proved to be zinc silicate  $ZnSiO_3$ ; it is a *pyroxene* isomorphous with the mineral *enstatite*  $MgSiO_3$ . It forms colourless prismatic crystals with rounded ends, belonging to the rhombic system. The same process was used by Ebelmen in 1851 for preparing magnesium silicate, but the product was partly monoclinic, partly rhombic in form. The method appears to be generally applicable to the preparation of similar, as well as complex silicates.—B. B.

*The Chemical Behaviour of Glass.* F. Foerster.  
Ber. 26, 2915—2922.

### A. The Action of Acids upon Glass.

EXPERIMENTS made with flasks of different kinds of lime-alkali glass proved that the loss of weight resulting after heating with diluted acids to  $100^\circ$  for six hours, was always the same with the same kind of glass, and was entirely independent of the strength of the acid or of its chemical composition. Sulphuric, hydrochloric, nitric, and acetic acids gave identical results. Only very strong acids had less effect than dilute ones, which again have less action than pure water. Similar results were obtained in working at temperatures of  $160^\circ$  and  $190^\circ$  with pieces of glass tubing enclosed in sealed tubes. The influence of the degree of concentration was, however, more pronounced than in the previous experiments, and was again in inverse ratio to the strength of the acid used. The dissolving action of the acids is therefore governed by the amount of water contained in them. Bearing in mind that the action of water upon glass consists in the liberation from it of alkali, which again further increases its vulnerability to water, the passive part played by the acid may be readily understood. In the case of glass containing an unusually large amount of alkali, the action of the acid, however, is more pronounced than that of pure water, the decomposition being analogous to that of many natural silicates. Lead glass exhibits the same peculiarities as lime-alkali glass, according to the proportion of lead contained in it. The nature of the base in combination with the silica likewise seems to influence the resisting capacity of the glass. Thus a zinc-lime-soda glass (Jena thermometer glass 16 III) was more attacked by concentrated acid than lime-soda glass of equivalent composition. The action of pure sulphuric acid is less strong than that of boiling water, but at very elevated temperatures its vapours produce a more marked effect.

### B. The Effect of the Atmosphere and of Water upon Various Kinds of Glass.

Dry carbonic acid does not affect glass, hence the action of the atmosphere primarily depends on the aqueous vapour contained in it. The liability of a glass to suffer changes by atmospheric influences can therefore be ascertained by estimating colorimetrically the amount of alkali separated on treatment with water. Glass, especially when rich in alkali, is capable of absorbing water which can only be completely expelled by heating to about  $500^\circ C$ . The water combines chemically, forming hydrates which represent the intermediate stage in the process of the decomposition of the glass by the action of water. An important part played by the alkali split off by water seems to consist in its facilitating the formation of such hydrates.

## C. Comparison of some Good Species of Glass with regard to Chemical Behaviour.

Nos. 7 and 8 are inferior soft varieties of glass commonly met with in commerce.

Of the good qualities Nos. 1—6, no single specimen shows an absolute superiority over the others. No. 1 closely resembles in its composition Stas' glass, which is still unsurpassed, and approaches the limit of that which is technically possible in the production of a glass capable of resisting the action of chemical agents.—F. M.

## PATENTS.

*Improvements in the Manufacture of Glazes, Enamels, and the like.* W. P. Thompson, Liverpool. From G. Leuchs and C. Leuchs, Nuremberg, Germany. Eng. Pat. 9611, May 13, 1893.

SILICA in glazes may be partly replaced by titanic acid without becoming coloured, provided the fusion be conducted in an oxidising atmosphere. The resulting glazes are said to be more fusible than those containing an equivalent of silica, and to be more resistant to corrosive agencies,

and also to possess a high specific gravity, good lustre, and a large coefficient of expansion. The latter quality allows of their use direct upon iron-ware, which has hitherto generally been coated in two operations, the underglaze having a suitable coefficient of expansion and the upper being resistant to acids. When a moderate amount of titanic acid is used, the glaze is transparent, and when a large quantity is employed an opaque glaze or enamel is produced. A typical mixture for the former is made from 15 to 30 parts of nitrate of soda, 116 of soda, 33 to 50 of carbonate of lime, 60 to 360 of quartz, 62—83 of boric acid, and 20 to 80 of titanic acid, while one for the latter is composed of 15 to 30 parts of nitrate of soda, 116 of soda, 100 of carbonate of lime, 60 to 180 of silicic acid, and 80 of titanic acid. Variations in the mixtures and the addition of coloring oxides are also claimed.—B. B.

*Waffer China Mosaic.* J. H. Bale, London. Eng. Pat. 22,362, November 22, 1893.

A LAYER of kaolin or clay is placed upon a suitable base or plate, such as a tile or sheet of metal, painted with coloring oxides, covered with glaze, and fired. The coloured glazed sheet thus produced is removed from the plate and used for mosaic work.—B. B.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*The Influence of Temperature on the Tensile Strength of Metals.* M. Rudeloff. Mitt. Königl. techn. Versuchs. 11 [6], 292.

See under X., page 520.

## PATENTS.

*Improvements in and connected with the Glazing of Bricks and like Articles.* W. Crookes, London. Eng. Pat. 9381, May 10, 1893.

Most commercial glazed bricks and tiles are made of fire-clay, and the present patent is concerned with the substitution therefor of ordinary non-refractory bricks appropriately glazed. Three types of brick are described, consisting of various mixtures of non-refractory clays, sand, and

glazeous materials. Five glazes or enamels are also mentioned containing red lead, silica, kaolin, carbonate of soda or other alkaline salts, arsenic, and tin oxide, which are used in various proportions, according to the nature of the required product. The glazes are fused, ground, and applied to the bricks in the usual manner.—B. B.

*Improved Method of Manufacturing Hydraulic Cement.*  
G. W. A. Stein, Wetzlar, Germany. Eng. Pat. 475,  
January 9, 1894.

IN order to render the usual preliminary crushing of cement clinker in stone-breakers unnecessary, the patentee adds 5 to 30 parts of granulated blast-furnace slag to 100 parts of the ordinary raw materials for the manufacture of hydraulic cement, and burns the mixture in the ordinary way, obtaining a product which is granular and brittle and can be fed direct to the grinding machinery without passage through a stone-breaker. By the use of a larger proportion of slag, e.g. 30 to 125 parts to 100 of cement raw materials and modifying the process of burning, a product can be obtained similar to hydraulic lime or Roman cement, or Portland cement.—B. B.

## X.—METALLURGY.

*The Influence of Temperature on the Tensile Strength of Metals.* M. Rudeloff. Mitt. Königl. techn. Versuchs.  
11 [6], 292—330.

THE tests were made on wrought iron, mild steel, copper, Delta metal (cast and rolled), and manganese bronze (4 per cent. rolled and 15 per cent. cast). No analyses of the samples are given. The temperatures adopted were the ordinary temperature of the room, 100° C. obtained by a steam jacket, 200° C. by naphthalene vapour, 300° C. by naphthylamine vapour, and 400° C. by a metal bath. In all cases the whole of the turned length of the specimen in which the fracture was to occur, and in addition a portion of the screwed end of the specimen by which it was held, were exposed to the hot bath to minimise lowering of temperature of the specimen by conduction through the screwed jaws of the testing machine. No tests of the actual temperature of the specimen as distinct from that of the bath are recorded. The gist of the results is as follows.

In the second table hereafter given, a comparison is made between the chief mechanical properties of the specimens at the ordinary temperature taken as a standard, and at the higher temperatures mentioned. In order to translate relative figures into absolute numbers, the following data are necessary for each of the metals tested at the ordinary temperature:—

TABLE I.

Material of Test Piece.	Elastic Limit.	Tensile Strength. (on 30 mm.)	Elongation (on 30 mm.)	Reduction of Area.
	Kilos. per Sq. Mm.		Per Cent.	
Wrought iron.....	26.3	35.3	35.3	55.0
Mild steel.....	27.3	41.8	34.4	50.6
Copper.....	26.9	20.1	17.9	54.6
Delta metal (rolled) ..	14.8	42.7	41.5	37.5
"    (cast) ....	9.7	32.9	21.9	24.8
Manganese bronze (4 per cent. rolled).	13.6	29.1	40.7	67.7
Manganese bronze (15 per cent. cast).	14.9	35.7	31.3	43.7

Calling each of these results 100, the figures obtained at the higher temperatures have the following values:—

TABLE II.

Material of Test Piece.	Temp.	Elastic Limit.	Tensile Strength.	Elongation (on 30 mm.)	Reduction of Area.
Wrought iron	100	100	110	54	87
	200	67	134	57	83
	300	64	138	94	90
	400	59	91	140	109
Mild steel	100	99	108	56	86
	200	88	125	56	69
	300	60	114	98	93
	400	48	92	92	52
Copper	100	95	92	66	103
	200	81	81	61	96
	300	56	70	75	78
	400	30	48	47	18
Delta metal (rolled)	100	112	92	110	109
	200	110	72	106	148
	300	75	50	158	151
	400	9	16	196	148
Delta metal (cast)	100	97	100	126	97
	200	119	82	134	118
	300	80	62	270	176
	400	17	20	146	100
Manganese bronze (4 per cent. rolled)	100	87	92	94	103
	200	85	89	93	97
	300	88	80	91	83
	400	70	71	39	30
Manganese bronze (15 per cent. cast)	100	100	92	79	80
	200	95	94	100	98
	300	102	93	91	79
	400	89	77	98	75

The following are the chief conclusions drawn from these results, regard being had to the fact that they apply primarily to the particular specimens tested, and are not necessarily to be accepted without modification for the varieties of metals examined generally.

Wrought iron and mild steel show a similar decrease in elongation up to 150° C., and a corresponding increase in tensile strength up to 250° C., indicating that the injurious influence of increase of temperature up to the latter point on the working quality of the metal is as true for wrought iron as it is generally known to be for mild steel. Above 300° C. wrought iron exhibits a decrease in tensile strength and increase in elongation, whereas mild steel, though also diminishing in tensile strength, suffers a decrease in elongation. It follows from this that the temperature below which wrought iron is liable to injury in working may be set at 300° C., whilst for mild steel a higher limit must be adopted.

With cast Delta metal the elongation increased but slightly up to 200° C. and then considerably to 300° C., after which point a sudden fall took place, whereas rolled Delta metal at 200° C. gave values nearly 50 per cent. in excess of those obtained at the ordinary temperature, with a decrease from 200° C. to 300° C., and a further large increase as the temperature again rose. The deductions to be drawn from these relations are that in the case of the samples tested the most suitable temperature for working

the cast metal is about 300° C., while the rolled metal is not in a fit state for being subjected to mechanical work from 200°—350° C. Should this difference of the rolled from the cast metal be valid generally, the first heat used in rolling from the cast state should be of lower temperature than further heats for subsequent work on the metal.

**Manganese bronze** (4 per cent. rolled) is most fit to be worked at the ordinary temperature, its elongation being then greatest. The large diminution in elongation between 250° and 400° C. explains the fact (well recognised in practice) that this alloy is red-short. As far as the figures go, which were obtained for 15 per cent. cast manganese bronze, it appears that the mechanical properties of the alloy are not much influenced by rise of temperature, and any one of the temperatures used in the investigation is suitable for the working of the material.

The appearance of the surface of the broken test-pieces, pieces of Delta metal (cast and rolled) and manganese bronze (4 per cent.) indicated that the metal had drawn out more uniformly at the higher temperatures, a phenomenon which the author ascribes to an alteration of molecular state analogous to that exhibited by brass which has been softened by heating and quenching. A similar increase in softness and uniformity should therefore be produced by heating these alloys to 250°—300° C. and quenching. Microscopic examination is suggested for settling this question of change of state.

Passing from the consideration of the working properties of these metals and alloys to that of their qualities as structural materials, the chief point to be regarded is the limit up to which extension and the load producing it, are proportional. The variations in this value caused by alteration of temperature are not included in the figures quoted in the foregoing tables, but are given in the following diagram, in which A is the curve for mild steel, B for wrought iron, C for rolled Delta metal, D for manganese bronze (15 per cent.), E for east Delta metal, F for copper, and G for manganese bronze (4 per cent.).

It being conceded that the load on a structural material should not exceed this limit so that no permanent deformation may occur, the significance of these curves is at once apparent. In those cases where rise of temperature raises the limit, regard must also be had to the alteration of other properties, notably the elongation and ultimate strength by the same rise.—B. B.

#### Certain Ternary Alloys. Part VIII. C. R. Alder Wright. Proc. Roy. Soc. 55, 130—139.

THE author has previously shown (this Journal, 1892, 492, and 1893, 449) that the ordinary book statements respecting the miscibility of melted aluminium and cadmium are incorrect, and that so far from alloying together in all proportions, they are only miscible to a very limited extent. He now finds, as the mean of a number of observations, that at temperatures averaging near 725° C. a mixture of

aluminium and cadmium separates into two binary alloys of the following compositions:—

	Heavier Alloy.
Aluminium.....	67.22
Cadmium.....	32.78
	100.00
	Lighter Alloy.
Aluminium.....	96.61
Cadmium.....	3.39
	100.00

Addition of varying quantities of tin to mixtures of these two metals at the average temperature 725° C. gives rise to a series of pairs of "conjugate" ternary alloys, precisely comparable with those similarly produced with lead (or bismuth) and aluminium (or zinc) with tin as "solvent" metal. The critical curve obtained on plotting the results, lies well inside that obtained with aluminium-lead-tin at 800°, indicating that the replacement of lead by cadmium diminishes the area representing mixtures of the three metals incapable of forming a single homogeneous fluid. The same remark applies also to the substitution of cadmium for bismuth, the temperature being the same throughout. No irregularity of outline in the aluminium-cadmium-tin critical curve was noticed, nor any peculiar conformation of tie-lines, suggesting the existence of definite metallic compounds; unlike the tie-lines in the case of aluminium-lead-tin alloys, where the lower lines slope in one direction and the upper ones in the other, the change of slope being apparently due to the formation of the definite compound,  $\text{SnPb}_3$ . With cadmium or bismuth (in conjunction with aluminium and tin) the direction of slope of tie-lines is the same, viz., that shown by the upper tie-lines of the curve where lead is present, and opposite to that shown by the lower ones.

Mixtures of aluminium and lead (or bismuth) with antimony as "solvent" metal kept fused at 850°—900° separate into pairs of fluid conjugate alloys in a perfectly well-defined way as long as the amount of antimony present does not exceed a certain proportion of the total mass (some 30 or 40 per cent.). When, however, the antimony is present in sufficiently large quantity relatively to the aluminium, solid matter forms during the period of tranquil fusion necessary for the separation from one another by gravitation of the two ternary alloys produced; and this causes the topmost and lowermost portions of the total mass to become abnormal in composition. The effect of this is to produce an excrescence or horn-like projection at the upper part of the critical curve when the results are represented graphically. The solid matter thus separating appears to be the definite antimonide of aluminium previously described by the author (this Journal, 1892, 492), indicated by the formula,  $\text{AlSb}_3$ ; the existence of this compound (found by Roberts-Austen to fuse at nearly the same temperature as gold, about 1,045° C.) has since been corroborated by D. A. Roche (Moniteur Scientifique, 1893, 269), who appears to have been unacquainted with the previous work on the subject. So far as the lower normal portions of the critical curves are concerned, the usual rule holds, viz., that the curve where bismuth is a constituent lies inside of that where lead is present instead, *ceteris paribus*. In the case of the lead alloy curve, there is nothing irregular about the conformation of this lower normal portion; but with the bismuth alloy curve a strongly-marked notch or inward depression is noticeable, the maximum extent of which occurs nearly when the bismuth and antimony present are in the ratio indicated by the formula,  $\text{Sb}_2\text{Bi}_3$ ; precisely as in the parallel case of zinc-bismuth-antimony alloys. Doubtless, therefore, a definite antimonide of bismuth of this composition exists. As regards the direction of slope of tie-lines, it is noticeable that aluminium-lead-antimony and aluminium-bismuth-antimony alloys both furnish tie-lines sloping in the same direction as that exhibited by zinc-lead-antimony alloys; whereas the slope with zinc-bismuth-antimony alloys is in the opposite direction.—C. R. A. W.

*Plant for Granulating Slag.* R. H. Terhune. School of Mines Quarterly, 1894, 15 [2], 108-110.

THE slag for which the plant was designed was from a lead blast-furnace, and the chief object of the adoption of granulation was to facilitate the removal of the slag. The plant is of the type usual for iron blast-furnace slag in this country. The slag is run into a trough 2 ft. wide and 6 in. deep, lined with cast iron plates 1 in. thick, and received in flowing water, the trough having an inclination of  $\frac{1}{4}$  in. per foot. This trough fronts all the furnaces the slag of which is to be granulated, and thence extends to a settling pit 8 ft. deep, whence the slag is raised by an elevator with buckets of malleable cast-iron, and delivered into trucks, or a storage bin, as may be required. In running the slag into the trough the operator is warned of the need of cutting off the stream by sharp explosions due to small portions of matte accompanying the slag. The granulated slag is brittle, and will pass through a  $\frac{1}{4}$ -in. mesh. It makes fair ballast for railways, but would be better for this purpose if coarser and more coherent. An incidental advantage of granulation is that the sampling and weighing of the daily output of slag are more easily performed, than if that material were allowed to solidify *en masse*; thus also control of the working of the furnace is facilitated.—R. B.

*The Reduction of Aluminium as a Scientific Problem.*

Alfred H. Bucherer. Eng. and Mining J. 1894, 315-316.

As there is no agent capable of reducing alumina by a single reaction, we turn of course to methods which make possible its reduction by several steps. The only compounds which permit of such gradual reduction are the anhydrous halogen salts, viz.: fluorides, chlorides, bromides, iodides, and further the sulphide. One would then naturally reduce the oxide to one of these compounds. And we know that except with the fluoride we have to overcome the affinity of the oxygen for aluminium by calling into play two agencies, the one with a tendency to combine with the oxygen of the alumina, and the other with the aluminium. A typical reaction of this sort is the formation of the chloride—

The other halogen compounds are formed in a similar way. In 1890 the author demonstrated that a similar reaction can be effected at a white heat for the production of the sulphide—

In case of the halogen salts reduction can be effected by alkali metals. The reduction of aluminium chlorides, or rather the anhydrous double chlorides of sodium and aluminium, was for some time the exclusive method used for the production of aluminium. After a very carefully and long continued development of this method, it has been superseded, and we can confidently assert that neither the chloride, the bromide, nor the iodide will ever be used for the production of aluminium, for we can never expect to obtain them cheap enough to compete with the present process, independently of the present high cost of the sodium required for the reduction. It has appeared for some time as though the reduction of the fluoride by sodium offered commercial advantages; but in view of the cheapness of the present method this can only be possible if the cost of sodium could be very considerably lowered, and we must also take into consideration that the reduction of the fluoride, as well as its regeneration by the action of the sodium fluoride on aluminium sulphate, are based on reactions which offer great difficulties, for they are not complete. As to the chemical reduction of the sulphide, it is not possible to produce pure metal, as appears from a series of experiments which the author has made. Tin and iron seem to be the only agents capable of reacting on aluminium sulphide, but the product obtained is of no value. An experiment performed by the author for the reduction of aluminium sulphide by zinc, although its result was negative, is of some interest. After having tried the experiment at temperatures obtainable in furnaces, he resorted to electrical heat. A cylindrical rod of carbon  $\frac{3}{4}$  in. in diameter and

1 ft. in length was hollowed out, filled with a mixture of granulated sulphide and zinc, and the ends closely fitted into large carbon cylinders, 3 in. in diameter, which latter in their turn were connected with the terminals of a dynamo, and a slanting position given to the cylinder. In passing a strong current of 20 h.p., the rod was brought to a dazzling whiteness and was kept so for 20 minutes. It is interesting to note that the temperature was so high, that when, at the end of the experiment, the carbon was examined, it was found to be bent as a result of accidental strain. No aluminium had been produced, but the larger part of the zinc was found in the upper part of the tube, where it had condensed, the larger carbons acting as condensers. The zinc did not contain a trace of aluminium, although the conditions had been most favourable. It appears, then, that the aluminium cannot be economically produced chemically, since we have considered all methods, and the electrical methods only remain.

The reduction of aluminium compounds by the electrolysis of aqueous solution will never become an economical process for producing aluminium, as too much energy is wasted. This loss of energy is due to two causes: first, to the high voltage required, and secondly, to the small output, which latter, due to recombination, is not at all proportionate to the product of the number of amperes by the time. It goes without saying that with aqueous aluminium salts polarisation is excessive.

Before passing on to the discussion of the electrolysis of molten aluminium compounds, some general peculiarities of molten electrolytes observed in an extended series of experiments, are mentioned. The high temperature at which electrolysis is effected, the corrosive character of the molten substances, the different states of aggregation in which the metal is deposited, require different technical appliances, which in their turn influence the conditions of electrolysis. As it is necessary to make the electrolytising vessel the cathode, and as the carbon cylinders forming the anode have small surface, it follows that there is comparatively small current density at the negative electrode, which circumstance has a marked influence on the reactions going on, especially where there is danger of reversed action by which the metal re-enters the electrolyte as an ion. It is worthy of mention that, in experimenting, the electrolysis of molten compounds often fails for no other reason than that the density of the current has been too small.

It is an experimental fact that under certain conditions of temperature, and when there is a large excess of sodium fluoride, aluminium is capable of reducing sodium, or, what amounts to the same thing, sodium will not reduce aluminium fluoride in the presence of a large excess of sodium fluoride. Now in the present process we have actually aluminium in the presence of sodium fluoride contained in the cryolite, and as a matter of fact we find that the output of the metal is small if the relative amount of sodium fluoride be large, so that by adding aluminium fluoride to the cryolite we increase the output, and we effect the same result by increasing the current density, for it is evident that if more metal be deposited on the square inch the relative proportion of sodium fluoride which would be involved in the reaction, is reduced. It follows then that the output will be greatest when the current density at the cathode is great and when there is an excess of aluminium fluoride over that contained in the cryolite. This observation is entirely borne out by actual experiment.

A peculiarity of molten electrolytes, which at the beginning of electro-metallurgical art appeared to offer almost insurmountable difficulty, is their corrosive action on the electrolytising vessels. It is certainly very striking that, for instance, molten common salt passes easily through a cast-iron vessel of an inch thickness if the latter be at a dark red heat. The chemical activity of the dissociated ions of the common salt, which is enormously increased at the high temperature, accounts for the fact that no ordinary metallic vessel can withstand their aggressive action. This phenomenon confirms the modern hypothesis of electrolytes, for although the iron—in case of an iron vessel—does not ultimately combine with the chlorine ions of the sodium chloride, yet the chlorine ions in contact with the iron for an instant combine with it, and then immediately re-combine

with the stronger sodium ions. This continuous attack results in an entire disintegration of the iron. It is well known that it was only after applying internal electric heat, namely, by fusing and keeping in fusion the electrolyte through the heat generated by its own resistance to the passage of the current, that the electrolysis of molten compounds became an industrial possibility.

The electrolysis of molten aluminium compounds we can divide into three classes: first, the electrolysis of molten halogen compounds; second, the electrolysis of alumina dissolved in a molten solvent; and third, the electrolysis of the sulphide. Little need be said about the electrolysis of molten halogen compounds, or rather double compounds, of aluminium and an alkali metal, as there is no possibility of their ever competing with the method by which the alumina is directly reduced. This is self-evident. As to the second method of decomposing the oxide dissolved in a molten solvent, it is noteworthy that there are only three substances which in a state of fusion are capable of dissolving alumina. These are borax, cryolite, and lithium oxide. Borax is unsuitable, because in passing a current there is obtained an alloy of aluminium and boron, or boron alone—depending on current density. Cryolite is a solvent used in the present method. So much has been said about the present process that it will suffice to say that from a scientific and economic standpoint it is altogether the best method, and that the chief cost being that of the ore and of electrical energy, the development of the process will largely depend on the cheapening of the ore manufacture and the saving of electrical energy, which at present is about five times the amount theoretically required.

The fact that molten lithia dissolves alumina was discovered by the author, but although lithia is an excellent conductor in its molten condition, and though its affinity for oxygen, to judge at least from the heat of formation, and from the fact that lithium reduces silica at a temperature of 203° centigrade—neither the hydrate nor the oxide can be reduced by carbon—appears to be greater than that of any other element, yet the author has not hitherto succeeded in reducing aluminium by electrolysis in a molten bath of lithia containing alumina dissolved. The great cost of lithia appears at any rate to exclude its commercial use in the aluminium industry; nevertheless it would be interesting from a scientific standpoint if aluminium could be reduced in this way.

It remains to speak of the electrolysis of aluminium sulphide, patented by the author in Germany. As yet the electrolysis of the sulphide, although it offers some advantageous features, has not been able to show commercial superiority over the present method.

There do not exist any other compounds of aluminium that can be reduced electrolytically. And it appears that the development of the aluminium industry will depend rather on improving the present method than on any attempts at finding new processes, for we have seen that—perhaps with the exception of the fluoride—there are no compounds of aluminium existing that offer any probability of serving as a material for the industrial production of the metal. (See this Journal, 1883, 368.)

#### *The Separation of Metals from their Dilute Solutions.*

F. Mylius and O. Fromm. Ber. 27, 630.

See under XI., page 527.

#### *Results of some Trials made to Test the Extraction of Gold by Dilute Cyanide of Potassium with Different Samples of South Australian Gold Ores.* G. A. Goyder. Report to the South Australian School of Mines and Industries for 1893, 4—24.

**Method of Procedure.**—After digestion the solution of cyanide was displaced by water, and the ore washed till almost free from cyanide. The portion collected was evaporated to dryness and fluxed with a little litharge, and the resulting lead button cupelled, the gold and silver being parted, and weighed.

**Effects of Salts of Copper and Iron.**—Such tailings, as well as the one from which they were derived, involve a considerable loss of cyanide, which combines and forms double salts with the basic salts of iron and copper present, and thus prevents it from dissolving the gold.

**Effects of Washing with Water before Extracting.**—Nearly double the weight of the tailings in water was used for the washing before adding cyanide solution. Even then all the soluble salts of iron were not washed out. Though a stronger solution of cyanide was used, the extraction of 49 per cent. is very low.

**Beneficial Effect of Circulating Solution.**—Continuous circulation of the cyanide solution was found very beneficial, quite apart from time or extra time of contact. A continuous circulator was devised by the author for the laboratory, and is figured and described.

**Rapid Extraction of some Ores.**—Some, such as the Mount Torrens Central ores, though simply crushed and containing all the coarse gold and concentrates, were extracted to the extent of 85 per cent. of gold in only four hours, the cyanide liquor circulated amounting in weight to 27 per cent. of that of the ore treated.

**Effect of Uneven Packing of Wet Ore.**—Great stress is laid on the necessity for placing the ore evenly and so as to avoid channels in the percolators or leaching vats.

**Effect of Coarse Gold.**—Coarse gold is as a rule only dissolved by cyanide after long circulation.

**Observations of Rate of Solution of the Gold.**—A speck of gold only just visible to the naked eye in a good light was picked out of a sample. It measured 0.001 of an inch in its smallest breadth; taking the thickness at 0.001 of an inch, it would be 250 times as thick as gold leaf, and would take 3½ days (83 hours) to dissolve in dilute cyanide of potassium under favourable circumstances. This shows that coarse gold should be removed from the ore before it is subjected to the cyanide process, since only the finest gold is dissolved.

**Long Circulation.**—One lot was circulated for a week, and 91 per cent. of gold was extracted.

**Washing Out Cyanide Solution.**—A sample was saturated with 27 per cent. of its weight of 1 per cent. cyanide and allowed to stand 17 hours. Results of percolation were:—

First solution and first volume of wash yielded 6 dwt. 8 grs. of gold per ton.

Second volume of wash water yielded 4 grs. of gold per ton.

Third volume of wash water yielded ½ gr. of gold per ton.

It is thus evident that the cyanide solution of gold is quickly and thoroughly washed out of the ore by water. It is also found that in the case of ores not being packed evenly the washings must be prolonged in order to extract all the gold.

Twenty-four samples of South Australian ores were tried, and it was found that all except the "Eureka," could be advantageously treated by the MacArthur-Forrest process after having been passed through a battery fitted with the ordinary appliances for saving gold.

In working the cyanide process the following points are recommended for attention:—

1. The ores should be crushed so as to produce a minimum of slimes.
2. The ores should be packed evenly in the vats, and lightly.
3. The solutions should be allowed to percolate continuously, as the gold is dissolved much more rapidly when the solution is moving than when at rest.
4. Solutions containing about ½ per cent. of potassium cyanide are strong enough for most ores.
5. Ores containing copper or other metal forming double cyanides, require a stronger solution or a greater volume of the weak solution.
6. Ores containing double salts, which form double cyanides with KCy, should be treated with water to dissolve out the soluble salts, before cyanide treatment. If not, loss of cyanide results.—W. S.

*The Separation of Blende from Pyrites.* W. P. Blake. Trans. of the Amer. Inst. of Mining Eng., Aug. 1893; and Proc. Inst. Civil Eng. **115** [2], 61—63.

IN south-west Wisconsin large deposits of zinc ore occur in the form of sheets of blende and pyrites (marcasite), sometimes well separated, but often as a close mixture, which cannot be brought up to the proper standard for reduction by mechanical methods alone, the specific gravity of the two minerals being so nearly the same that a marketable concentrate cannot be obtained by jigging. Experiments in this direction were made by the Wisconsin Lead and Zinc Company, who erected two mills and turned out hundreds of tons of concentrates of different sizes, which were unsaleable owing to the high percentage of pyrites retained. Galena could be easily separated from such mixed ore, but blende and pyrites were inseparable, and neither was obtained in a marketable form, as the smelters of zinc ores in the Mississippi valley will not take those containing more than 7 per cent. of iron. The method devised by the author is similar to that adopted in tin dressing, the metallic minerals being first separated from the bulk of the earthy waste as a mixed concentrate, which is subjected to an oxidising heat in a Branton calciner, in which the revolving bed, instead of being a smooth cone, is stepped, forming a series of annular shelves 18 ins. broad, with a maximum diameter of 16 ft. at the bottom. The ore is fed through a funnel in the apex of the roof, and is discharged at the circumference of the bottom shelf. This treatment entirely or partially decomposes the pyrites, while blende and galena are scarcely, if at all, changed, the former mineral scarcely losing its brilliant lustre, whilst the latter is hardly tarnished. Beyond a slight breaking up of the fragments of blende by decrepitation, there is no change of form in the concentrate except as to the pyrites, which suffers a change of bulk with the loss of its sulphur. The pieces of marcasite swell, expand, crack, and exfoliate, becoming more bulky than before roasting; and the blende fragments, being reduced in size by decrepitation, a condition favourable to separation by jigging is obtained. The products of the latter operation are clean blende, or "dressed jack," and tailings, consisting chiefly of red oxide of iron, which serve as the basis of an excellent metallic paint, their value being enhanced by containing a small proportion of oxide of zinc. Any lead ore present is removed in the first compartment of the jigging machine, the furnace operation having split off the blende, leaving the galena free. This is another important advantage, as blende containing more than 2 per cent. of lead is unfit for the production of the best spelter. From a first raw concentrate, containing blende, 25 per cent.; pyrites, 25 per cent.; and galena, 5 to 10 per cent.; and the remainder dolomite and flint, after roasting and second jigging, marketable blende is obtained of a very good quality, assaying in the best samples over 62 per cent. of zinc, less than 3 per cent. of iron, and 1 per cent., or in some cases below  $\frac{1}{2}$  per cent., of lead.

Complete and even roasting is essential for the success of the process, as every particle of bisulphide of iron must be decomposed. Even a remnant or kernel of unchanged pyrites will cause the fragment to remain with the blende. The outer oxidised coating may be broken off and pass into the tailings but the unchanged part will not go over, and such imperfectly roasted ore will have to go back to the furnace. It has been found that by proper manipulation the pyrites, when reduced to the magnetic form by the removal of the second atom of sulphur, may be left in a condition to be attracted and removed by the magnet. Experiments have been made upon this subject by Mr. J. W. Meier, who finds that mixed ores, with 33 to 36 per cent. of zinc and above 10 per cent. of iron, may, by roasting in a muffle and magnetic separation, be easily converted into concentrates with 50 to 54 per cent. of zinc and only about 4 per cent. of iron. The chief difficulty is the conversion of the whole of the pyrites to the magnetic state, as fragments fully converted into ferric oxide cannot be removed by the magnet, and a partial reduction of these from ferric to magnetic oxide by the action of solid or gaseous carbon seems to be necessary after roasting. This method might probably be applied with advantage to the

ferruginous calamines of Wisconsin, it having been proved to be perfectly successful with similar ores at Monteponi, in Sardinia.

*Sulphur in Cast Iron.* W. J. Keep. Trans. Amer. Inst. of Mining Eng., Aug. 1893; and Proc. Inst. Civil Eng. **115** [2], 69—70.

THE conclusion finally reached is that the proportion of sulphur retained by grey cast iron cannot materially injure the iron except by increase in shrinkage, which in the extreme ends seems to be from 0.168 to 0.194 in. per ft. The general testimony is that most of the sulphur present in pig iron is lost in re-melting, and that it is impossible that it can be re-absorbed to any damaging extent from the fuel. The influence of sulphur is diminished by increase of carbon or silicon. In wrought iron, which is practically free from these elements, a small amount of sulphur is said to do great harm, and such iron will take up sulphur in considerable quantity. In steel containing less than 1 per cent. of carbon and practically no silicon, a few hundredths per cent. of sulphur cause decided injury. When carbon increases to saturation as in white cast iron, not more than 0.50 per cent. of sulphur can be retained, and as silicon increases, producing graphitic carbon, it is still more difficult to find sulphur in the metal, as it will not absorb it from the outside.

The influence of sulphur on all cast iron is to drive out carbon and silicon, to increase shrinkage, and in general to reduce strength, but in practice sulphur will not enter the iron in the foundry to a sufficient extent to realise these defects. When, as happens sometimes, iron which was grey when put into the cupola comes out white with increased shrinkage and ebull, and often with decreased strength, the change is due to loss of silicon, and can be remedied by re-melting with an appropriate addition of ferro-silicon or other highly-silicified metal.

That highly sulphurised iron cannot be produced in practice is evident from the fact that ores are used (in America) containing over 3 per cent. of sulphur with fuel containing nearly 1 per cent. of the same element; but all smelters are agreed that not more than 0.75 per cent. of sulphur can be found in white iron, 0.25 per cent. in mottled, and not more than a few hundredths in grey foundry iron. The experiments show that 0.50 per cent. of sulphur will not exert any appreciable deleterious influence, and even that may be at once corrected by a slight increase in silicon.

Remembering that the only noticeable effects would be to slightly increase the shrinkage, the above conclusion seems to be proved by the fact that, in a foundry working with a substantially uniform mixture, returning from 25 to 40 per cent. of its metal to the cupola to be re-melted over and over again each day, the castings will almost invariably have a less shrinkage than the average of the pig iron used, and yet they will probably contain more sulphur and less silicon than the pig iron originally did.

*Experiments on the Behaviour of Phosphoric Acid in the Blast-Furnace, and the Influence of Phosphorus on the Composition of Pig Iron.* N. Kjellberg. Jernkontorets Annaler, 1892, 180; and Proc. Inst. Civil Eng. **115** [2], 71—72.

UNTIL recently it has been generally supposed that the whole of the phosphorus present in a blast-furnace charge passed into the iron, and that no appreciable quantity was to be found in the slag. There must, however, be a point at which the iron becomes saturated, and the phosphorus must then combine with the slag. With basic slags, and at low temperatures, much of the phosphoric acid passes into the slag; but it is not easy to determine in advance how much of this impurity will be ultimately found in the slag, and how much in the iron.

In Sweden there are large deposits of iron ore rich in phosphoric acid, especially at Grängesberg and Gellivara, and the author's experiments were undertaken with the view of finding the best method of utilising these ores.

There are three main causes which determine the proportion of phosphorus in slag or metal, namely, the amount of phosphorus in the charge, the temperature in the blast-furnace, and the basicity or acidity of the charge. The experiments were made in a small blast-furnace with quantities of 1 tons of ore in each case. The ores were smelted without previous calcination, and their percentage of phosphorus varied from 0.2 to 3.6. Each sample of ore was run with basic and acid slags, and the difference in the composition of metal and slag determined in each instance. The author deduces the following conclusions:—

(1.) When the phosphorus in the ore does not exceed 1½ per cent., neither the low temperature in the blast-furnace nor the higher or lower proportion of silica in the slag has any appreciable influence on the reduction of the phosphoric acid. The greater part of the phosphorus of the ore combines with the iron, so that ultimately 90 to 95 per cent. is found in the pig iron and 5 to 10 per cent. in the slag.

(2.) When there is more than 1½ per cent. of phosphorus in the ore there appears to be a more definite division of the phosphorus between slag and iron. Up to a percentage of 3.5 the greater proportion of the phosphorus unites with the iron; but with a basic charge from 40 to 50 per cent. may be driven into the slag. With a high temperature and acid slag, about 95 per cent. of the phosphorus may be brought into combination with the iron.

(3.) There appears to be no volatilisation of phosphorus in the blast-furnace in the case of ores containing up to 3.6 per cent.

(4.) The carbon in pig iron diminishes as the phosphorus increases, especially when the latter is above 3 per cent.

(5.) The proportion of silicon also decreases as the phosphorus rises, and a pig iron containing 4 per cent. of phosphorus may not contain more silicon than steel. The specimens of iron containing most phosphorus were so brittle that the ingots could be broken by a light blow from a hammer.

In the case of ores containing 50 per cent. of iron, the pig iron from the blast-furnace will contain about double the percentage of phosphorus existing in the ore. When the percentage of iron in the ore amounts to about 60, it is possible to produce an iron with a smaller proportion of phosphorus when the basic process is employed. For foundry pig iron, with an amount of phosphorus not exceeding 1 per cent., 60 per cent. ores should be chosen with not more than 0.6 per cent. phosphorus. For pig iron to be treated by the Thomas basic process, and containing at least 2 per cent. of phosphorus, the percentage of that impurity in the ore should not be less than 1.6.

*The Action of Concentrated Acids on Certain Metals when in contact with each other.* George J. Burch and J. W. Dodgson. *Proc. Chem. Soc.* 1894. 137. 84—87.

IN 1790, James Keir (*Phil. Trans.* 1790, p. 367) announced that a mixture of strong nitric and sulphuric acids could be used for stripping the silver from old-plated copper goods. The authors have investigated the chemical and electrical phenomena of this and other reactions of the same type, and now present a preliminary account of their work.

*Experiments with a Silver-Copper Couple.*—A sheet of "pure" silver was cut into strips, which were scraped bright, bent into a U-shape, and weighed. To each was fitted a similar strip of copper, carefully cleaned and weighed, the whole forming an elliptical ring, held together by the elasticity of the metals. A number of test-tubes arranged in a water-bath contained the mixed acids diluted with various proportions of water. Each ring remained under the surface for 17 minutes, and was then rapidly removed, wiped, washed, and weighed. The liquid was not stirred during the experiment.

**SILVER-COPPER COUPLE, in a Mixture of 1 part NITRIC ACID of rel. dens. 1.436 with 5 parts H<sub>2</sub>SO<sub>4</sub> of rel. dens. 1.84 with various PROPORTIONS of WATER ranging from 1 to 10 molecules per molecule of H<sub>2</sub>SO<sub>4</sub>. Temperature 20° C.**

10	0.6342	0.0300	0.00833	0.05835	0.2594	1.2055

In the stronger solutions, a yellowish-white powder separates from the silver, and a clear, heavy liquid of strong refracting power streams from it. Little or no gas is evolved.

During a few seconds after immersion the copper is covered with a white froth. This clears away, and the surface remains bright. Probably, nearly all the loss of copper occurs at this stage. When the dilution is represented by 8H<sub>2</sub>O + 11H<sub>2</sub>SO<sub>4</sub>, nitrous fumes first begin to appear. It will be observed that the amount of silver dissolved is least with 5H<sub>2</sub>O, after which it increases again, and that the copper, which is practically untouched at 3H<sub>2</sub>O, is now rapidly attacked. At temperatures above 50° C., the results are somewhat different.

*Magnesium-Silver Couple.*—In a mixture of 10 parts sulphuric acid of rel. dens. 1.84 with 1 part nitric acid of sp. gr. 1.436, the magnesium retained its brilliant appearance during an hour and 20 minutes, while the silver dissolved steadily. No gas was evolved. The magnesium lost 0.0015 grm., and the silver lost 0.1167 grm., the ratio of the loss per unit area being—

Ag : Mg :: 61.5 : 1.

*Electrical Phenomena.*—The influence of each metal on the rate of solution of the other is in most cases strongly marked. With the copper-silver couple the resistance increases rapidly on short circuit, apparently at the surface of the copper. The quantity of current is not proportional to the weight of silver dissolved.

**Sodium and Sulphuric Acid** (rel. dens. 1.84).—Sodium alone is less rapidly attacked by strong sulphuric acid at 16° than by water. The action was moderate but steady. Bubbles of gas were freely given off, and very little heat was evolved. The sodium was completely dissolved in about 20 minutes, a small quantity of a whitish substance being formed near it towards the end of the process.

The contact of another metal with sodium exerts an influence on the rate and manner of its solution in strong sulphuric acid. In most cases the action of the solvent is much retarded. The gas evolved comes from the *entire surface* of the platinum, carbon, or iron, when these substances are employed, and is given off freely from first to last. No bubbles appear on the sodium, which is clean and bright. The iron-sodium couple lasted 40 minutes, the platinum-sodium about two hours, and the carbon-sodium was still acting slowly after eight hours. In this case gas came from the sodium, and none from the carbon for the first 10 minutes after the initial effervescence was over. Then the sodium became quiescent, and bubbles rose from the carbon. Sulphur was separated after a while.

With lead and tin the action was similar, but much slower. The sodium was not so clean and the liquor became very turbid.

The tin acquired a brownish-yellow coating and the lead assumed a grey colour. It was several days before the sodium disappeared.

Zinc exerts comparatively little restraining action, but makes a very turbid solution.

An aluminium-sodium couple, weighted with a glass rod to sink it, evolved torrents of gas, and after about five seconds the sodium caught fire.

A magnesium-sodium couple similarly weighted gave a flash of light as it touched the liquid. Then, for about three seconds, there was a copious evolution of gas, and the sodium burst into flame while completely submerged.

With the cadmium-sodium couple the action was extremely slow. Fewer bubbles came from the sodium than from the cadmium, which became covered with a brown film. The liquor was turbid.

Coming now to those metals which produce a markedly different effect.

Nickel scarcely evolves any gas, but is soon coated *near the sodium* with a brownish film, while a few bubbles rise from the sodium. Antimony exerts the most powerful restraining influence of any substance yet tried. The initial action is very small. Bismuth behaves in much the same way. Both these metals become coated with a film near the sodium. Very little gas is evolved, and what there is comes from the sodium, which remains for days undissolved.

Silver in contact with sodium turns dark. Very few bubbles appear on either metal, but the sodium, which is quite clean, is visibly smaller after two hours.

Thus a magnesium-silver couple is almost inert in the acid, and a sodium-silver couple acts very slowly, but a magnesium-sodium couple bursts into flame, whereas either metal separately would be a long time in dissolving.

Copper evolves no gas, but becomes coated with the gas given off from the sodium, and presents a reddish fawn-coloured film. The sodium is brilliantly clean, and during the first stage of the reaction evolves gas slowly.

*The Oxidation of the Alkali Metals.* Wilmot Holt and W. Edgar Sims. Proc. Chem. Soc. 1894 [137], 95.

POTASSIUM and sodium (and probably lithium) are not attacked by perfectly dry oxygen, and may be distilled in it, without undergoing oxidation.

## PATENTS.

*Improvements in Extracting Gold and Silver from Ores and the like.* J. S. MacArthur, C. J. Ellis, and the Cassel Gold Extracting Company, Limited, all of Glasgow. Eng. Pat. 5218, March 10, 1893.

IN the MacArthur-Forrest process as heretofore used there is formed a sulphide soluble in the cyanide which retards and objectionably affects the action of the cyanide on the precious metals. This sulphide is now rendered inert by adding to the solution or to the ore, or to the mixture of ore and solution, a salt or compound of a metal which can form a sulphide practically insoluble in the cyanide. The following salts may be used, preferably in the order named, viz., salts or compounds of lead, such as plumbates; carbonate, acetate, or sulphate of lead; salts or compounds of other metals, such as sulphate or chloride of manganese; zincates; oxide or chloride of mercury; and ferrie hydrate or oxide. The proportion to be used in any case will depend on the proportion of soluble sulphide present, which is ascertained by a practical test on the laboratory scale.—A. W.

*Improvements relating to the Pickling of Metals and Alloys to remove Oxide and other Impurities from the Surface thereof.* A. J. Smith, Kingston-on-Thames. Eng. Pat. 6137, March 22, 1893.

INSTEAD of cleaning the surface of metals by the ordinary method of dipping in acids, the author uses the articles to be cleaned as the positive pole of a battery, the negative pole being either carbon or wire gauze electro-plated with silver and preferably covered with amorphous platinum black. The bath consists of dilute sulphuric acid with sometimes a depolariser such as a nitrate or chromic acid. By this means it is stated that the plates are better cleaned, with little, if any, "pitting" of the metal, and also that the offensive odours usually evolved are prevented when chromic acid is used. The electric current produced by this means is utilised by being passed into storage batteries for lighting purposes.—A. W.

*Improved Alloys for Use in the Manufacture of Wire.* A. Macdougall, Glasgow. Eng. Pat. 7301, April 10, 1893.

THE alloy consists of nickel, 2 to 3 parts by weight, zinc 10 to 14, and copper 83 to 88. The copper and nickel are melted together and the zinc afterwards added. The alloy is manufactured into wire in the usual manner; and the object of the above composition is to diminish the liability to corrode in making endless wires for paper-making machines and other purposes.—A. W.

*Improvements in the Manufacture of Steel, and in the Refining of Fluid Iron.* B. H. Thwaite, London. Eng. Pat. 8456, April 27, 1893.

THE ladle and a small converter are fixed at the ends of a bell crank lever with the open ends at right angles to one another, so that the swinging of the lever through a quarter of a circle backwards and forwards will alternately bring the mouth of one above the other. The whole is mounted on a carriage, a quantity of metal from the cupola is run into the ladle, the crank lever is turned, and the metal poured into the converter; herein it is blown with air or oxygen, and the ferro-manganese added if necessary. When the metal is ready the crank lever is turned back again and the metal poured once more into the ladle, which is then taken to the mould. The apparatus is more particularly applicable to and useful in the rapid treatment of comparatively small quantities of metal.—A. W.

**Improvements in the Treatment of Zinc Plates to be used as Substitutes for Lithographic Stones.** E. Forrest, New Southgate, and F. L. H. Bucholz, London. Eng. Pat. 8800, May 2, 1893.

The zinc plates, as pure as can be obtained commercially, are passed through highly-polished cold rollers to remove any surface marks. They are then placed in dilute nitric acid (1 part acid to 100 parts water). This brings to the surface of the zinc a blackish mass containing impurities, which is removed by washing with water and scouring with pumice powder. This is repeated until the nitric acid and water no longer produces any appreciable amount of the blackish mass. Such treatment renders the plates absorptive and removes all matters deleterious to lithography. They are then dried and subjected to the sand-blast process to produce a grained surface. When this has been done they are placed in a bath composed of 4 parts of nitric acid, 1 part of phosphoric acid, and 500 parts of water, after which they are washed with water. A second and sometimes third treatment with this solution and washing with water is resorted to. In some cases, when fine-grained plates are required, a bath containing 1 part of sulphuric acid in 100 parts of water is used instead of the mixture of nitric acid, phosphoric acid, and water, as the former in no way interferes with the grain. Finally, the plates are washed with a weak solution of alum (1 part of alum to 50 parts of water), after which they are dried and are then ready for use. The plates produced by this process are absorptive and sensitive to grease, and of a similar nature to lithographic stones. Moreover, they retain their light colour after being submitted to the aforesaid baths.—A. W.

**Improvements in Treating Malleable or Wrought Iron.** J. H. Ladd, London. Eng. Pat. 9406, May 10, 1893.

"CRYSTALLISED wrought-iron" is changed to a fibrous condition by subjecting it to the action of a gaseous composition consisting of air, hydrocarbon vapour, and water vapour in a state of combustion. The mixture should contain 3.395 grains of water vapour and 45 grains of hydrocarbon vapour (benzene) to the cubic foot. By subjecting the iron to this mixture during combustion, it is said to become carburised before it reaches its welding point, the amount of carburisation depending upon the length of treatment.—A. W.

**Method and Apparatus for Extracting Gold and Silver from their Ores by the combined Action of Amalgamation and Centrifugal Force.** A. Trug, Verespatak, Hungary. Eng. Pat. 25,071, December 30, 1893.

THE apparatus consists of an inverted cone-shaped vessel open at the top and fixed to a vertical shaft rotated by a pulley. Within the vessel is a distributing disc fixed to the shaft and provided with radial ribs and a circular rim. The ore-sludge is distributed by this and thrown with an upward velocity on to the inner surface of the cone-shaped vessel. This surface has annular ribs formed on it, which prevent the mercury falling down to the bottom of the vessel. By the rotation of the vessel the ore is carried upwards over these ribs to the top of the vessel, whence it is thrown off into an annular trough. The mercury containing the gold is washed down into the bottom of the vessel and through perforated plugs. Electricity may be used to maintain the mercury surface active, and this is done by connecting the tubes feeding the distributing disc with the positive pole of a current generator, the negative pole being connected with the surface carrying the mercury.—A. W.

## XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

*The Separation of Metals from their Dilute Solutions.*  
F. Mylius and O. Fromm. Ber. 27, 1894, 630—651.

The authors have made elaborate researches on the phenomena occurring in the precipitation of one metal by another in dilute solution, and in the electrolysis of solutions of similar tenuity. Their conclusions are summarised under the following heads:—

### 1.—Precipitation of one Metal by another.

- (1) Metals are capable of union with each other at the ordinary temperature, at the moment of deposition.
- (2) Alloys are formed by the action of a metal upon the dilute solution of one electro-negative to it, and their formation can only be explained on electrolytic grounds.
- (3) The composition of the alloy corresponds with the solvent capacity of the negative for the positive metal, under the conditions of the experiment.
- (4) The resulting alloys are generally porous and may be either black and apparently amorphous, or crystalline; in the latter case their composition usually corresponds with some simple atomic relationship.
- (5)  $\text{Cu}_2\text{Cl}_2$ ,  $\text{AuCl}_3$ ,  $\text{Cu}_2\text{Sn}$ , and an alloy of platinum and lead can be obtained crystallised in the wet way.
- (6) Alloys obtained in this manner are in no way different from other substances insoluble in water in respect of their mode of formation and decomposition.
- (7) The alloys are decomposed and new alloys are formed by treatment with solutions of their negative metals.
- (8) The alloys are decomposed by acids with the evolution of hydrogen and separation of their negative constituent, behaving in this reaction like couples of low E.M.F.; the decomposition is generally incomplete.
- (9) The action of oxidising agents is usually confined at first to the positive constituent of the alloy, sharp separations being sometimes obtained in this manner.

### II.—Precipitation by an Electric Current.

- (1) The heavy metals may be separated more or less easily from their dilute solutions in the form of black, porous, apparently amorphous precipitates.
- (2) Silver and copper precipitated in this manner may occlude hydrogen during the passage of the current, but the greater part of the gas escapes on opening the circuit.
- (3) Silver and copper precipitates exhibit spontaneous change into the crystalline state, frequently accompanied by the evolution of hydrogen.
- (4) The conversion of the black into the crystalline modification is hastened by the action of metallic salts, acids, and oxidising agents, the metals being in this respect analogous to the alloys.
- (5) The black variety of copper containing hydrogen is essentially different from Wurtz's copper hydride.
- (6) An electrolytic method of formation of copper hydride no more exists than does a process of preparing the same body by means of zinc.
- (7) The black precipitate frequently observed on the zinc of a Daniel's cell consists of a copper-zinc alloy. The same body separates on the copper plate when the cell is exhausted.—B. B.

### PATENTS.

*Improvements in and connected with Galvanic Batteries.* C. A. J. H. and H. E. R. Schroeder, London. Eng. Pat. 23,101, December 15, 1892.

The patentees claim an exciting fluid—to be used without a porous diaphragm—consisting of 0.5 to 1.5 parts of nitric acid, 2.5 to 4 of sulphuric acid with 10 to 18 of water, all by volume. They also claim the construction of "comb-like" carbon electrodes, by clamping a number of carbon plates together with suitable carbon distance-pieces, by a single bolt with nuts and washers protected by gilding or platinising. They claim further the use generally of gilded or platinised connections; the application of slate screws and nuts to galvanic batteries; and porous pots indented with deep hollows to reduce their resistance.

In certain cases it is proposed to have in one of the end cells of the battery, as many zinc or carbon plates as there are lamps to be lighted, and to run a separate wire between each lamp and its plate. The other terminals of the lamps to be joined by a single conductor to a single electrode at the other end of the battery.

It may be mentioned that in a single fluid cell working at 60° C., the inventors state that an electrolyte containing 1 volume of nitric acid, 3 of sulphuric acid, and 2 of water, is suitable for current densities of 5 amperes per sq. inch.

—E. T.

*Improvements in the Manufacture of White Lead.* S. Z. de Ferranti, London, and J. H. Noad, East Ham, Essex. Eng. Pat. 23,572, December 21, 1892.

See under XIII., page 532.

*Improvements in the Production of Alkali, and in Apparatus therefor, the said Apparatus being Applicable for Electrolysis generally.* J. Hargreaves, Farnworth-in-Widnes, and T. Bird, Cressington, Liverpool. Eng. Pat. 5197, March 10, 1893.

In carrying out this invention a solution of sodium chloride on one side of a porous diaphragm is subjected to the action of an electric current, while a gas, such as air and moisture, acts on the opposite or cathode side of the diaphragm; or where the production of a carbonate is required carbonic acid gas and moisture may be admitted to the cathode side, and if a combustion engine be employed for driving a dynamo for supplying the electric current, the carbonic acid gas for acting on the alkali may be derived from the products of combustion given off by the engine, any moisture required being evaporated and conveyed to the cell by the aid of heated air or other gas. To prevent polarisation metallic oxides or catalytic material, such as platinum, together with oxygen or an oxidising substance, may be applied to the cathode. A containing electrolytic cell is shown divided by a horizontal porous partition in contact with the cathode, above which the solution to be decomposed is retained, and below which is a space for the gas to be applied to the cathode as above described. The apparatus is of the type shown in Eng. Pat. 18,871, 1892 (this Journal, 1894, 250).—J. C. R.

*Improvements in and in Making Electrolytic Apparatus.* J. Hargreaves, Farnworth-in-Widnes, and T. Bird, Cressington. Eng. Pat. 5198, March 10, 1893.

This refers to the combined cathode and diaphragm described in Eng. Pat. 18,039 of 1892 (this Journal, 1894, 255). They propose to form such diaphragm by first depositing on the wire gauze a material such as lime mixed with a fibrous substance like asbestos, and then drying.

The whole is then dipped in silicate of soda or potash, whereby the lime is converted into an insoluble silicate binding the fibrous material to the gauze.—E. T.

*Improved Methods for Effecting the Electro Fusion of Steel and its Alloys.* B. H. Thwaite, London. Eng. Pat. 6000, March 21, 1893.

This invention relates to a method of effecting the fusion of ferro-carbon of steel and its alloys, by which fusion is effected economically and rapidly, and in such a way as to produce a continuous flow, without producing deterioration of the metal produced, which is described as follows:—"I superpose one crucible over another, the latter however may be an ordinary open hearth steel furnace hearth, or it may be a chamber having a calcined basic or acid lined hearth or bottom similar in method of formation to that of an open hearth furnace. At the bottom of the upper of the two crucibles there is an opening provided by and through which any fused metal in this crucible can flow into the lower crucible or chamber described as rapidly as fusion takes place; through the sides of the crucible I pass positive and negative carbon electrodes, which are so arranged that the scrap or other steel can be easily fed continuously. The voltaic arc, as well as the resistance to the current set up by the metal to be fused, soon provides the fusion temperature, and the metal flows into the second chamber, across which I may fix two or more electrodes, so that in this second chamber there is also established a fusion of steel melting temperature, by which the steel can accumulate in a molten condition. When sufficient metal has accumulated the tap hole is opened and the metal runs into a ladle to be cast into ingots in the ordinary way." There are drawings illustrating this invention, and methods of preventing oxidation, of effecting reductions of other metals, producing alloys, are also dealt with.—J. C. R.

*Improvements relating to the Pickling of Metals and Alloys to Remove Oxide and other Impurities from the Surface thereof.* A. J. Smith, Kingston-on-Thames. Eng. Pat. 6137, March 22, 1893.

See under X., page 526.

*A Process and Appliance for Electrically Treating Gaseous and other Bodies, a New Compound Gas made by such Process, and Apparatus for Producing and Consuming said Gaseous Product.* T. G. Hall, Chicago, County of Cook, U.S.A. Eng. Pat. 6551, March 28, 1893.

This invention, embracing 19 claims, is said to depend upon gaseous electrolysis produced in compound gases by certain electric couples, such as copper and iron, insulated from each other by a porous material, and built up as a stack in a chamber or chambers, which are heated, and through which the gases to be operated upon are passed, resulting in decomposition and recombination, producing a different order of things, said to be useful, for details of which the specifications must be consulted. Eng. Pat. 6551A 1893, is referred to.—J. C. R.

*Improvements in Secondary Batteries.* V. C. Doubleday, London. From M. Sussmann, Neuruppin, Germany. Eng. Pat. 6780, March 30, 1893.

The active material consists of a finely-divided metal—such as lead—or metallic oxide, mixed into a paste with india-rubber or gutta-percha solution, 5 to 15 per cent. of powdered pumice or other porous material being added.

The conductors used are flat plates from which numerous tongues are stamped out so as to stand up at an angle to the surface. The active material being spread over the whole plate and compressed, is held in position by these tongues, and at the same time a large conductive area of lead plate is provided.—E. T.

*Apparatus for the Artificial Production of Chalybeate Water.* O. March, London. Eng. Pat. 2362, May 10, 1893.

This invention relates to apparatus for the production of chalybeate water by means of electrolysis, water being employed as the electrolyte, with a pair of electrodes of iron, the anode of which supplies iron to the solution, similar to that found in many natural chalybeate waters, and has valuable medicinal properties.—J. C. R.

*Improvements in Connection with Electrolytic Apparatus.* H. Y. Castner, London. Eng. Pat. 10,584, May 30, 1893.

This patent refers especially to Eng. Pat. 16,046 of 1892 (this Journal, 1893, 768) where a sodium amalgam is formed by electrolysis of sodium chloride, and afterwards removed to another vessel to allow of the extraction of the sodium as caustic soda.

By the present invention the process is made automatic by using an electrolytic cell provided with compartments communicating with each other. This is caused to rock slightly by machinery at a suitable rate, so that at one time the mercury is in one compartment and amalgamating with the sodium formed by electrolysis, but a short time later is in another where the sodium is being extracted. A depth of mercury of about  $\frac{1}{2}$  inch is mentioned.—E. T.

*Improvements in Primary Voltaic Batteries.* W. Walker, jun., Birmingham, and F. R. Wilkins, Handsworth. Eng. Pat. 10,942, June 5, 1893.

A porous pot containing a zinc electrode suspended by lugs from its top edge, is surrounded by a wire gauze tube. Between this and the porous pot is packed gas carbon, powdered where in contact with the porous pot, in coarser granules next the gauze. The whole is supported in a tray so that any liquid percolating through the porous pot may keep the carbon moist, but if in excess it may collect in this tray. The carbon having in this way an enormous surface exposed to the air, takes up oxygen which acts as a depolarising agent to combine with the hydrogen produced during action in the cell.—E. T.

*Improvements in Apparatus for Electrolysis of Water.* Siemens Bros. and Co., London, and F. A. Obach, Old Charlton. Eng. Pat. 11,973, June 17, 1893.

From the top of a vessel constructed preferably of cast-iron, a cylinder projects downwards below the surface of the electrolyte, and is continued by an iron wire gauze tube to the bottom of the cell. The vessel is thus divided by the cylinder and gauze tube—which acts as diaphragm—into two co-axial compartments in which the two gases collect separately. The electrodes are tubes or shells of iron inside and outside the gauze diaphragm and suitably protected against the possibility of contact with it.

The electrolyte is a solution of caustic soda or potash, or a mixture of the two.—E. T.

*Improvements relating to the Electro-deposition of Metals.* J. Rudholzner, Munich, Germany. Eng. Pat. 2900, February 9, 1894.

“ARTICLES which are to be coated with metal by electrolysis and some parts of which are subject to greater wear than other parts necessitate care in the distribution of the metallic coating.” This invention sets forth improvements in obtaining varying thicknesses of deposits on articles to be coated with metal by electrolysis, by arranging in the electrolytic bath between the article to be coated and the anode freely suspended plates of insulating material, provided with larger or smaller apertures, so that the parts of the article which are directly opposite the apertures receive a thicker coating of metal than those parts which are protected (screened) more or less from the direct action of the current by the plates suspended in front.—J. C. R.

*An Improved Electric Insulating Compound.* L. Bærenhielm and A. Jernander, Stockholm, Sweden. Eng. Pat. 3045, February 12, 1894.

See under XII., page 531.

*Improvements in the Heating of Gases by Electricity.* W. Donaldson, London. Eng. Pat. 3223, February 14, 1894.

This invention relates to methods of heating gases by electricity by passing them through an elongated chamber or tube, in contact with an internal coil of wire or other partial conductor carrying an electric current, the resistance and resulting temperature being arranged so that it is of least intensity at the point where the gas enters and of greatest intensity where the heated gas issues.—J. C. R.

## XII.—FATS, OILS, AND SOAP MANUFACTURE.

*Crude Wool Grease and Lanolin.* Chem. Ind. 17, 149—155.

ORDINARY sheepswool (unwashed) contains 12—23 per cent. of moisture, 31—43 of actual wool fibre, 3—23 of dirt, and the remainder, some 28—42 per cent., of a mixture of potash soaps and fatty matters the majority of which consists of cholesterol, isocholesterol, and analogues and ethers thereof (such as cholesterol benzoate, stearate, &c.) and some waxy matters, more particularly ceryl cerotate. The isolation of the fatty matters in a very crude form was described by Dioscorides, the product being designated *oxyppus* by Pliny in the early years of the Christian era; but the separation in a more complete way of the cholesterol and waxy constituents is of entirely recent origin.

The use of solvents for extracting the fatty matters, e.g., carbon disulphide, petroleum spirit, “benzine,” amyl alcohol, &c.), although promising enough *a priori*, has in practice not been found to work satisfactorily, the wool fibre being generally damaged during the operation of freeing it from the adherent solvent after the grease has been washed out, or otherwise deteriorated as regards its fitness for spinning; accordingly, the extraction methods and apparatus of Richter, O. Braun, Moisan, and others have now only historical interest. Similar remarks apply to some of the earlier methods adopted for utilising to some extent the waste liquors of wool washing, e.g., those of Kurrer, v. Westraumb and others, where the grease was precipitated by milk of lime, and the lime soaps, &c. thus obtained subjected to dry distillation for illuminating gas-making; although this process is still applicable to the residues left on filter pressing the grease recovered from the liquors by addition of acid. Bräsin first employed the fatty acids obtainable from the liquors for soapmaking, the lime precipitate being prepared by treating under 8 atmospheres pressure, and distilling off the unaltered cholesterol by superheated steam, the residual lime-soaps being decomposed by hydrochloric acid. Viallette and Vinchon endeavoured to convert wool-grease entirely into saponifiable matter by heating the dry grease with solid alkali to 250°—300°, air being excluded by means of an indifferent gas or superheated steam; in this way not only are all free fatty acids and glycerides converted into soaps, but further the cholesterol ethers are saponified and the fatty alcohols formed more or less completely converted into acids under the influence of the alkali with disengagement of hydrogen; so that on decomposition of the mass with acids, a mixture of various fatty acids results with but little of any other organic constituents. Thus ceryl alcohol forms a cerotate; and so on.

At the present time, the wash waters of woollen factories are usually simply treated in tanks with sulphuric acid, the quantity of which is best regulated by alkalimetrically

examination of an average sample of liquor; usually about 0.4 per cent. of acid of 66° B. is requisite. The liquors are generally of two kinds mixed together, viz., the liquors from the "leviatans" or washing machines for raw wool, consisting essentially of watery soap solution with emulsified wool-grease suspended therein; and the purer liquors obtained from the further washing of spun and woven goods where soap is employed as detergent, whilst oily matter applied to the wool to facilitate spinning, &c. (olive oil, &c.) is washed out. After acidulation, waste steam may conveniently be blown in to facilitate the separation of the fatty acids, &c. ("magma") from the watery fluid. After draining and filter-pressing (first cold, then hot) about 50 per cent. of the crude magma remains as a dirty press-cake of which the following may be taken as the average composition (Deite). Water, 10.66. Fat, 34.74. Organic matters, 22.37. Sand and dirt, 30.32. Soluble silica, sulphuric acid, phosphoric acid, oxide of iron, alumina, lime, magnesia, alkalis—1.91. Total, 100.00.

The other half that passes through the filter is a watery fat requiring refining. As a preliminary operation the grease is boiled for an hour with its volume of water containing 2 or 3 per cent. of sulphuric acid, for which purpose wooden vats provided with steam coils are best suited. After standing at rest for two hours the watery liquor is run off, and the grease boiled up with plain water to wash out entangled acid. After standing at rest for 12 or 14 hours the grease is carefully drawn off from above and dehydrated by blowing superheated steam through the mass. The dark product requires bleaching, for which purpose potassium bichromate and sulphuric acid give good results according to some, whilst this is not confirmed by others. The bleaching liquor consists of 1 part  $K_2Cr_2O_7$  of acid at 66° B. and 10 to 12 parts water; sodium bichromate has lately come into use instead of the potassium salt, being cheaper and more soluble. Instead of sulphuric acid, the equivalent quantity of hydrochloric acid may be employed. In any case the temperature should not exceed the fusing point of the grease by more than a few degrees, otherwise the emulsifying of the grease is more difficult, and the bleaching action correspondingly hindered, larger visible globules and droplets being formed instead of minute or microscopic ones. The grease and bleach liquor are well agitated together for 20 minutes by hand or machinery; the green aqueous fluid is run off, and the purified grease washed by agitation with hot water; it then consists of a mixture of free fatty acids, glycerides, and cholesteroid bodies.

Vohl's process for extracting grease from wool-washing liquors consists in treating the liquors with calcium chloride solution, so as to form insoluble lime soaps which carry down with them the cholesteroid bodies, &c. The precipitate is collected and decomposed by hydrochloric acid, and the fatty matters that separate again boiled up with water containing a little acid; on standing, three layers form, viz., watery solution of hydrochloric acid and calcium chloride at the bottom, clean grease at the top, and an emulsion in between, the working up of which presents difficulties. Solution of fatty matter therefrom by light petroleum spirit ("benzine"), and distillation to recover the grease and spirit, may be employed. Magnesium sulphate may be used instead of calcium chloride. Neumann employs milk of lime as a precipitant, followed up by addition of magnesium sulphate and ferrous sulphate; a perfectly clear effluent is thus obtained on filter-pressing, the press cake being then treated with acid as before.

The grease resulting from one or other of these processes was formerly employed as a lubricating material or for the manufacture of coarse soaps; and more recently was frequently worked up by distillation, and separation of so-called "oleine" and "stearine" (respectively liquid and crystalline constituents). The increasing demand for lanolin, however, renders it advantageous to extract the cholesteroid bodies by separation from the free fatty acids, &c. This may be effected in various ways, usually depending on the conversion of the fatty acids into soaps insoluble in solvents (e.g., acetone), which readily dissolve the cholesteroids. O. Braun's process, however, is a mechanical one, the wool-fat emulsion in soap solution being

agitated in a centrifugal machine so as to separate the suspended grease from the soap-water, somewhat as in creams separation from milk. The wool liquors, for example, may be partially precipitated by alkaline-earth salts (especially calcium chloride), the precipitated lime-soap carrying down the cholesteroids, which may then be separated by means of acetone, which leaves the soaps undissolved. Or the grease may be previously separated, purified by solution in benzene, carbon disulphide, &c., so as to separate dirt, and then treated with acetone, &c., to dissolve out cholesteroids. Details as to the exact methods employed in the somewhat difficult and troublesome process of refining wool-fat are not obtainable from extant publications; the descriptions given in various patent specifications form a chaos, out of which it is difficult to decide accurately which points are, and which are not, of actual practical utility.

In commerce two preparations occur, substantially consisting of the purified cholesteroids, viz., "anhydrous lanolin" (*Lanolinum anhydricum* or *Adeps lanae*); and "lanolin," a product containing some 30 per cent. of water, obtained by kneading the anhydrous substance with water. The former should be perfectly neutral, not becoming rancid by exposure to air, yellowish-white in colour, and of the consistence of a stiff salve. It should be free from all traces of chlorine, metals, glycerol or glycerides, soaps, and saline matters; no mechanically intermixed impurities or colouring matters should be present, nor should it have any disagreeable odour. On rubbing on blue litmus paper no reddening should occur; no residue should be left when incinerated on platinum foil and it should be perfectly soluble in ether. The hydrated product should possess corresponding properties. Pure lanolin for medicinal use when melted in a steam bath with 5 parts of water for half an hour should be free from froth; the aqueous liquor should not give more than 0.02 per cent. of residue on evaporation, and the fat should melt at 38–40° C. 0.05 gm. lanolin, 5 cc. chloroform, and 5 cc. sulphuric acid should produce a deep brownish-red colour at the junction of the two fluids.

The peculiar absorptive action of the human skin as regards lanolin renders this substance specially useful as a medicinal unguent; on rubbing on to the top of the head corrosive sublimate lanolin salve (1 in 1,000), a metallic taste becomes perceptible on the tongue after a few minutes. An increasing demand exists for lanolin as a constituent of toilet and medicinal soaps, and for the introduction of certain sulphur compounds into the body it appears to be well fitted.—C. R. A. W.

#### Manufacture of Oil and Food from Peanuts. United States Consular Reports 1894, 44, 683.

The report deals with the trade in peanuts, as a source of oil and as a food, in Germany, where there is a considerable consumption of this material. The import of peanuts into Germany for 1893 was 20,973 tons, 7,040 tons coming from India; 8,471 tons from West Africa; and 5,431 tons from East Africa. The best peanuts brought into the market are from Senegal, and the worst from Madras. The following are recognised commercial grades. Senegal, 51 per cent. oil; Congo, 49 per cent.; East African, 49 per cent.; American, 42 per cent.; Bombay 44 per cent.; and Madras 43 per cent. The nuts are generally imported in the shell from West Africa and from America, but the kernel only is often shipped from East Africa and India. The saving of freight by this practice is counterbalanced to some extent by the greater tendency of the unprotected kernels to become rancid on the voyage. The shells, which amount to about 23 per cent. of the total weight of the dried nuts, are used in Germany for making paper and for cattle food. The oil is obtained by three crushings, the first yielding 40 per cent. of oil, the second 4 per cent., and the third 2–3 per cent. Cold-pressed oil from good peanuts is used for eating instead of olive oil, and fetches 14.75 to 26 dollars per 100 kilos. The last pressings go for soap-making and "other technical purposes, among which is included the 'fattening' of oleomargarine." The American peanut is larger, sweeter, and, when roasted, of better flavour than the others, but the oil is only of medium quality.

The oil-cake sells for 30—33 dollars per ton and is used for cattle-food, but is said to be too rich and oily for working animals, e.g., horses.

Peanut meal contains so large a percentage of nitrogenous matter that experiments have been made to determine its suitability for army and navy rations and as a cheap food for the labouring classes. Analysis of "peanut grits" made from the residue obtained after the expression of the bulk of the oil, showed it contained: nitrogenous matter, 47.26 per cent.; oily matter, 19.57 per cent.; non-nitrogenous matter (other than oil), 19.06 per cent. This, therefore is richer in nitrogenous matter than are soyabean which have been hitherto considered as a typically rich material of this class. As the wholesale price per pound of peanut meal is 4 cents, this material forms certainly a cheap nitrogenous food.—B. B.

### PATENTS.

*Laundry Glaze.* John Conroy, Bebington. Eng. Pat. 9433, May 11, 1893.

The use of the following mixture is claimed for the manufacture of a laundry glaze, viz.:—

	Lbs.
French chalk.....	35
Barilla ash soup.....	2
Borax.....	$\frac{1}{2}$
Resin.....	$\frac{1}{2}$
Water.....	15

This mixture is dried and powdered, or made into a paste, if desired.—J. J. K.

*Improved Process of Producing Consistent and Semi-consistent Fats and Oils without applying heat.* G. Pommerhanz, Vienna. Eng. Pat. 9882, May 17, 1893.

This is based on the property possessed by wool-fat or grease of incorporating with most salts, and of solubility in mineral oils, which are solidified by it. The degree of solidification is increased by the addition of caustic soda. Seventy lbs. of mineral oil are thoroughly mixed in an agitator with 20 lbs. of melted wool-fat, and 3 lbs. of caustic soda lye of 35° B. with 6 lbs. of common salt (dissolved in as little water as possible) are then added. A stiff yellow mass is formed, suitable for lubricating machinery, and greasing yarn or leather.—J. J. K.

*A Process of Improving or Preserving Oils and Fats.* E. Watel, Paris. Eng. Pat. 12,847, June 30, 1893.

This invention consists in the improvement of the quality and better preservation of oils, by eliminating from them volatile matters which impart odours or flavours, and traces

of water left in, when the oils are extracted by pressure or fusion. Two methods are described, intermittent and continuous. Fig. 1 shows the apparatus in which the oil is purified intermittently; the fatty material is heated in the steam jacketed boiler A to 140° F., when it is run through the pipe B into the closed apparatus C, in which a vacuum is maintained by the condenser D and the vacuum pump E through a pipe F. Dry steam is then introduced into C through the pipe H and the injector I, when the volatile matters and water are driven off into the condenser D.

The continuous method is shown in Fig. 2, where the melted fat or oil runs down a column C', and is met by the

Fig. 2.

steam entering the chamber C, through the pipe K. Vacuum indicators L, thermometer T, and glass plates G, enable the operation to be watched.—J. J. K.

*An Improved Electric Insulating Compound.* L. Baatnhielm and A. Jernander, Stockholm, Sweden. Eng. Pat. 3045, February 12, 1894.

This invention relates to the production of a compound, consisting chiefly of vulcanised stearin pitch, from the pitchy residuum obtained in the distillation of fatty acids, which is a good insulating material, but at the ordinary temperature it becomes soft and sticky, whilst in the cold it is brittle and cracks. To obtain a more suitable product, 74 parts of stearin pitch are mixed with 25 of sulphur, for a hard material, or 70 parts of stearin pitch, with 20 of linseed oil and 10 of sulphur, for a soft material, and respectively heated to a temperature of from 120° to 175° C.—J. J. K.

*A Superfatted Biniodide of Mercury Soap.* C. R. Ungworth, West Kensington, London. Eng. Pat. 12,884, July 1, 1893.

This is an improved medicated soap, for use in cases of infectious fevers, skin disorders, and disinfection generally. Any superfatted soap is dehydrated and thoroughly incorporated with about 1 per cent. of a solution of mercury biniodide in potassium or sodium iodide, and the mass compressed for the purpose of stamping into tablets.

—J. J. K.

Fig. 1.

### XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

#### (4.)—PIGMENTS, PAINTS.

##### PATENTS.

*Improvements in the Manufacture of White Lead.* S. Z. de Ferranti, London, and J. H. Noad, East Ham, Essex. Eng. Pat. 23,572, December 21, 1892.

This invention relates more especially to improvements on the process described in the specification of a former Eng. Pat. 6049, 1892 (this Journal 1893, 363). In this process acetate of ammonia is decomposed by electrolysis with lead electrodes, yielding a lead solution and caustic alkali, which is afterwards carbonated, when on mixing the two solutions white lead is precipitated. As the process was formerly conducted the whole of the lead could not advantageously be precipitated by the carbonated alkali, but a certain amount had to be left in solution, to be afterwards removed by the addition of chromic acid, by which the cost of production was increased. By means of the present invention the inventors claim the immediate precipitation of the whole of the lead in solution as white lead. This is effected by heating the lead solution and precipitating vessel lead from the hot solution, employing in the mixing vessel an excess of ammonia over and above that which results from electrolysis. The excess of ammonia is afterwards separated by distillation, the filtrate being sprinkled over a steam-heated coil, after the precipitated white lead has been previously separated by a filter press. Volatilised ammonia and any ammonium carbonate is thus condensed, whilst the acetate of ammonia solution is stored up for use again in the electrolyser, which is constructed of lead plates locked up together in a frame, as in a filter press, the plates being separated by porous diaphragms, which are made preferably of stout Willesden paper, insulated at the bottom to prevent irregular electrolytic action. In the electrolyser, with a series of cells with exit openings at the bottom, elastic bags distended by fluid within, are so arranged as to close these openings.—J. C. R.

*Improvements in Apparatus for the Manufacture of Metallic Pigments or Compounds, and in the Production of Lead and Zinc Pigments or Compounds and Combinations of these by Means of such Apparatus.* A. C. J. Charlier, Glasgow. Eng. Pat. 7119, April 6, 1893.

This patent is a continuation and enlargement of Eng. Pat. 7117, 1893 (this Journal, 1894, 407), air being introduced into the oxidising chamber of the apparatus under pressure, and the producer furnace being built in an elliptical instead of rectangular form. The plant is also used for the manufacture of "marine white," a mixture of lead sulphate and zinc oxide, by introducing into the furnace, together with the lead ore, some material containing zinc, so that the two may be volatilised and condensed together. It is, moreover, available for the preparation of zinc oxide or carbonate alone by heating the furnace up to the temperature of about 1,300° C., throwing in the zinc ore, and drawing the metallic fumes and furnace gases by means of an injector up a vertical tower and through a water condenser. In the water pumped off from the precipitated carbonate are found soluble zinc salts, which are precipitated by alkaline carbonates. The zinc carbonate may be used as a pigment or converted into oxide in the usual manner.

—F. H. L.

*Improvements in the Manufacture or Production of Lamp-black.* R. Irvine, Royston, Granton, near Edinburgh. Eng. Pat. 68, April 25, 1893.

TARS or oils rich in carbon are sprayed over incandescent coke, and the permanent gases so produced mixed with air and steam, or steam only, are burnt in the presence of a limited supply of air to produce lampblack.—F. H. L.

*Improvements in the Manufacture of Pigments.* O. Imray, London. From J. Sachs, C. E. Meier, and N. Gerstendörfer, New York, U.S.A. Eng. Pat. 166, January 3, 1891.

In order to make cotton and linen absorb certain dyes it is necessary to treat them first with albuminoid substances. Such a process is known as "animalising," and the inventors have discovered that a similar process may be employed in the case of mica and other minerals, which renders them available for use as the base of various pigments. The finely-divided mica is washed and introduced into a solution of egg albumen, dried, and then treated with steam at a temperature slightly above 100° C. to coagulate the albumen. So treated it will readily take up any aniline colour, no mordant being required, but for wood extracts aluminium or tin salts may be used. The albumen may also be coagulated by acid vapours or it may be replaced by a faintly ammoniacal solution of caseine. The dyed mica has a beautiful lustre, which may be increased and rendered more metallic by incorporating with it some well-polished metallic powder, such as bronze powder or bisulphide of tin, &c.—F. H. L.

### XIV.—TANNING, LEATHER, GLUE, AND SIZE.

##### PATENTS.

*Improvement in the Art or Process of Waterproofing Leather, and in the Compounds employed in the same.* E. H. Lewis, St. Louis, Missouri, U.S.A. Eng. Pat. 3615, February 20, 1894.

THE finished leather is made pliable and waterproof by coating it with a compound of rubber-paste or caoutchouc, 3 parts; spirits of turpentine, or its equivalent, 2½ parts; and naphtha or other volatile solvent, 2½ parts. It may be found desirable to sprinkle soap-stone dust or other absorbent material on the prepared side of the leather just before using it.—A. G. B.

*Improvement in the Art or Process of Waterproofing Leather.* E. H. Lewis, St. Louis, Missouri, U.S.A. Eng. Pat. 3616, February 20, 1894.

THE leather is immersed in a bath of equal parts of wax (beeswax, paraffin wax, or spermaceti) and a volatile solvent vehicle, such as naphtha, heated to 150°–170° F. for 5–10 minutes, and allowed to dry. When the leather has been tanned "under the chemical or hot liquor process," and therefore has a very dry grain, it is well to add turpentine to the bath; this will make the chemically-tanned leather pliable, so that it can be successfully operated upon by the channeling machine.—A. G. B.

*Process and Compound for Waterproofing the Soles of Shoes.* E. H. Lewis, St. Louis, Missouri, U.S.A. Eng. Pat. 3617, February 20, 1894.

THE following compound is applied over the welt and insole, or over the seams, joints, peg-holes, &c.:—2½ lb. of wax are melted and 3 lb. of powdered talc, stearite, or soapstone are mixed therewith; 4 pints of rubber-paste or caoutchouc (Brazilian gum) are then incorporated with the mass.

—A. G. B.

## XV.—MANURES, Etc.

## PATENT.

*Improvements in the Manufacture of Fertilisers.* J. J. Seldner and John Watson, jun., Baltimore, Md., U.S.A. Eng. Pat. 2624, February 6, 1894.

This relates to the utilisation of refuse hair, leather, and similar material in the manufacture of high-class nitrogenous manures. One method is to put the hair, &c., with a weak solution of sulphuric acid into a closed steam-jacketed digester, and heated by means of the steam jacket until there is a pressure of 30 lb. in the digester, when the water in the acid solution is vaporised; the fibre is destroyed, and a pulpy mass produced. Alkaline matter, phosphate rock, or bone is added to neutralise the free acid left in the mass, then the mixture is dried, and forms a nitrogenous manure containing about 3 per cent. of ammonia.

A preferable method is to mix the hair, &c., with dissolved bones or superphosphate of lime (which contains enough free acid to disintegrate the hair), with the addition of water, and stirring the mixture by an agitator in the digester during the heating.—J. J. K.

## XVI.—SUGAR, STARCH, GUM, Etc.

*Crystalline Levulin.* E. Schulze and S. Frankfort. Ber. 27, 1894, 65–66.

THE authors have isolated a carbohydrate by the process described in the preceding abstract from the stalks of rye gathered before the commencement of seed formation. It resembles levulin in most of its properties, but is crystalline—a difference which may perhaps be due to its superior purity. It is optically inactive, and does not reduce Fehling's solution; it gave numbers on analysis indicating the formula  $C_6H_{12}O_{11}$ . When treated with acid it yields levulose. Until the identity or otherwise of this carbohydrate with ordinary levulose is definitely settled, the authors propose provisionally to denote it  $\beta$ -levulin.

—A. R. L.

*Estimation of Calcium Sulphide in Animal Charcoal by means of Bromine.* P. Herrmann. Die Deutsche Zuckerind. 1893, 18, 225.

See under XXIII., page 546.

## PATENTS.

*Process for obtaining Para-phenetolcarbamide ("Dulcin").* J. Wetter, London, from J. D. Riedel, Berlin. Eng. Pat. 10,850, June 2nd, 1893.

See under XX., page 542.

*Improvements in Refining Sugar.* E. Langen, Cologne, Germany. Eng. Pat. 3782, February 21, 1894.

THIS is a process for obtaining an artificial massecuite by the admixture of syrup with raw sugar, and the subsequent subjection of the mass to crystallisation in motion. The syrup may be concentrated either before or after the introduction of the raw sugar.—A. R. L.

## XVII.—BREWING, WINES, SPIRITS, Etc.

*Dissemination of Saccharose in Seeds of Plants.* E. Schulze and S. Frankfort. Ber. 27, 1894, 62–64.

THE authors employ the method already described by one of them (Schulze, this Journal, 1893, 347) for the isolation of saccharose from seeds. The seeds are digested with 90 per cent. alcohol, and strontium hydroxide added to the alcoholic extract the precipitate being decomposed by carbonic anhydride. The saccharose was generally obtained in the crystalline condition, being purified by repeated crystallisation from dilute alcohol. It was identified by its form, taste, rotatory power, reaction with resorcinol after treatment with hydrochloric acid (levulose reaction), and its behaviour towards invertase and Fehling's solution. In this way saccharose has been recognised in the seeds of wheat, rye, oats, buckwheat, hemp, sunflower, pea, soja-bean, and coffee. Stirling and Morawski (Monatsh. Chem., 7, 76), have proved the presence of this carbohydrate in soja-beans, whilst Stenhouse, Graham and Campbell, and Ewell, showed that it occurs in coffee. Saccharose has likewise been recognised by numerous observers in the seeds of field-bean, scarlet-runner, barley, maize, pig-nut, hazel, wallnut, and almond; the author confirms its presence in these as well as Richardson and Crampton, to whom the observation is due that saccharose occurs in wheat germs.

The green pods of the pea contain saccharose, a fact of some interest, inasmuch as it is probable that the sugar passes thence into the ripe seeds where it is converted into starch.—A. R. L.

*The Preservation of Wines by means of Sodium Silicofluoride.* L. Surre. Monit. Scient. 1894, 3, 258.

THE author has detected in a wine, which he had occasion to examine for antiseptics, the presence of fluorides. A sample of the preservative employed was obtained, and found to consist of sodium silicofluoride.—H. T. P.

*Note on the Fermentation of Molasses.* J. Effront. Monit. Scient. 1894, 3, 161–165.

IN distilleries employing molasses as raw material serious losses frequently occur owing to the marked resistance to complete fermentation exhibited by particular samples. Fermentation in such cases proceeds very irregularly, and, when apparently complete, the lyes still contain considerable quantities of unaltered sugar. The potential loss of alcohol thus incurred must not be confounded with the losses arising from actual destruction of alcohol or sugar by the undue development of acid ferments, the use of inferior yeast, &c. The peculiarity in question is inherent to the molasses, and is generally ascribed to the presence of a free volatile acid (which retards fermentation), and, in a smaller degree, to an excess of salts (nitrates, &c.). The various means, based on this theory, suggested to render such molasses easily fermentable, all aim at removing the free acid, either by neutralisation or by boiling, with or without the addition of sulphuric acid, and subsequent neutralisation of the latter. According to the author, the benefit accruing from such treatment, although occasionally well marked, is very often nil. Experiments made with good and bad samples of molasses are quoted, which show that:—

1. There is practically no connexion between the percentage of volatile acid and the fermentability of molasses.
2. The removal of the acid is advantageous only when its amount is unusually large.

The cause of the non-fermentability of certain molasses must be sought elsewhere, and is shown by the author to be due to the presence of a particular micro-organism. This view is based on the following observations:—

1. A trace of difficultly fermentable molasses added to a solution of normal molasses renders the whole difficultly fermentable.
2. This effect is not destroyed by boiling the mixture.
3. The effect is greatest when inoculation is made before fermentation.

The author has succeeded in isolating the organism and finds it to be essentially anaerobic in character. Grown in a solution of molasses it forms small viscous masses, which under the microscope are seen to consist of aggregations of short rods embedded in a gelatinous medium. Cultures of the organism added to sterilised solutions of normal molasses rendered them in every case difficultly fermentable. The organism possesses in an eminent degree the power of resisting the influence of heat and antiseptics. Its suppression in worts by the liberal addition of antiseptics is, therefore, not practicable, since the large amount necessary would deleteriously affect the yeast. Its removal is best effected by some method of clarification. For this purpose, the solution of molasses is diluted to a strength of 18 Balling, slightly acidified, and treated with tannin at the rate of 25–35 grms. per 100 kilos. of molasses. The solution is then, preferably, raised almost to the boiling point and allowed to cool. The precipitate which settles carries with it all the bacterial cells, and the supernatant liquid when decanted off will be found to ferment quite normally. Pieric acid may also be used as precipitant with excellent results, but its presence is inconvenient in the subsequent production of "vinasses." Other clarifying agents, such as white of egg, alumina, &c., may also be successfully employed.—H. T. P.

*The Preservation of Wines by means of  $\beta$ -Naphthol Sulphonic Acid.* Sinibaldi. Monit. Scient. 1893, 7, 842–844.
